Dr. CARLO FORNANINI, whose death occurred quite recently, was born in Milan in 1847, and was graduated at Pavia in 1870. He at once became an assistant at the celebrated Ospedale Maggiore in Milan, remaining there in successive ranks until 1884, when he was made professor of clinical medicine in the University of Turin. In 1890 he received the same appointment in the University of Pavia, his alma mater, remaining there until his death. He was active at various periods as physician, surgeon, dermatologist, ophthalmologist, pathologist, and experimenter, which training made him a superior teacher in his terminal field of internist. He was founder of a medical periodical, *Il Policlinico,* not the present journal of that name, but one which subsequently became *La Gazetta Medica Italiana.* In 1912 he was made Senator. From 1882 until his death he was interested especially in the subject of therapeutic pneumothorax, with which operation his name is eponymically associated.

Dr. NICOLAS ACHUCARRO, a pupil of Ramon y Cajal, died recently. He was a young histologist, distinguished especially for his studies of the intimate structure of the nerve centers. He was a consummate technician, and his work on hydrophobia and general paralysis was well known to his colleagues. His greatest claim to distinction is his pioneer work on the neuroglia, and he was led by his finds to the belief that this tissue is an organ of internal secretion of capital importance for the central nervous system.

Obituary Notes.—Dr. SAMUEL FREDERICK ANDERSON of Brooklyn, N. Y., a graduate of the Long Island College Hospital, died at his summer home at Seaside Park, N. J., on August 5. He was assistant laryngologist to the Methodist Episcopal Dispensary of Brooklyn.

Dr. FERDINAND LESSING died at Philadelphia, on July 11, at the age of 81 years. He was graduated from Jefferson Medical College in the class of 1869.

Dr. FREDERICK LYMAN HILLS of Bangor, Me., died in New York City on July 30, aged 48 years. He was graduated from the College of Physicians and Surgeons, New York, in 1892, was on the staff of the Danvers State Hospital at Danvers, Mass., for several years, and later assistant superintendent of the New Hampshire State Hospital, superintendent of the tuberculosis sanatorium at Rutland, Vt., and since 1910 superintendent of the Bangor State Hospital.

Correspondence.

THE CHANGING VIEWS ON CANCER.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It is certainly very encouraging and hopeful to note the change which may be observed in medical periodical literature relative to the subject of cancer. The journals during the last year have been singularly free, that is relatively, from active surgical articles concerning this disease, and correspondingly full of those relating to the medical aspect of the question.

Thus, in the *Journal of the A. M. A.* for July 27 there was a long editorial on "Diet and Tumor Tissue Growth," and in the MEDICAL RECORD of the same date an article on "The Relation of the Proteins in Food to the Cause of Disease," with special reference to cancer. And now in this week's MEDICAL RECORD an article comes from England on "Cancer a Disease of Deficiency," and in *The Medical Times* for August one on "Does Analogy Exist Between Animal and Vegetable Tumors?" In this last article there is, in addition to a strong negative answer to the question, also a strong argument toward the constitutional or metabolic origin of cancer.

Is it not interesting that in several journals four different writers should at about the same time indorse and sustain a proposition which the surgeons have so long ignored? For in several writings I have already shown that it has repeatedly had strong support from able men for the past one hundred years at least. Surely light is beginning to dawn, and it is sincerely to be hoped that before long the rational therapy of cancer will result in a material reduction in the steady and alarming increase in mortality, which, as I have repeatedly shown, cancer has had under surgical care of late years.

L. DUNCAN BULKLEY, M.D.

NEW YORK.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MEDICAL PROFESSION UNDER A MINISTRY OF HEALTH—MEDICAL ETHICS AND PROFESSIONAL DISCIPLINE—THE ENGLISH COLLEGE OF SURGEONS.

LONDON, July 18, 1918.

IN the House of Lords on Wednesday last Lord Willoughby de Broke raised the question of the failure of the Government to redeem their oft repeated pledge to establish a Ministry of Health. Medical men are every whit as aware as any member of the public or any professional politician that the country is at war, and that the conduct of business is hampered thereby, in some directions by the absence of the natural leaders in special departments and in other directions by the enormous piling up of military and administrative work. None the less the Government should recognize that this excuse cannot be used forever and ever; already it has become a confession of weakness, and yet there can be no argument, other than that of inability to find the time, to justify (if justification it be) a delay in legislation which compels the nation to pay an enormous price in lives, and to put up with an infinite amount of preventable disease and misery. That the public and the medical profession are at one in desiring the early constitution of a Ministry of Health has been proved this week significantly by the fact that several schemes for a reorganization of the medical profession under a Ministry of Health have been brought forward and that they have received from the lay press an amount of attention which has not hitherto been accorded to professional subjects. The British public is now awake to the fact that anything which is of first class importance to the medical profession is of first class importance to themselves. These are the steps of thought that are being realized in their logical importance: (1) that a Ministry of Health is absolutely needed to guard the public health, but particularly to organize a service for the prevention of disease and for its treatment in the earliest stages; (2) that the administration of such a Ministry of Health must be largely in the hands of the medical profession, who are the only people who can lay down the best programs, visualize the places in which difficulties will occur, and deal in substance and in detail with the machinery of preventive and curative medicine; (3) that where so much depends upon the medical profession the organization of that profession in such a way that it can render the best professional services to the public is a matter of first importance.

It is being felt by all the more thoughtful members of the medical profession that the time has come when some sort of general opinion of the profession should be arrived at in answer to the attitude of an expectant public. The public should learn how, in the opinion of doctors themselves, the best services of the profession would be obtained under a Ministry of Health, so that when the actual proposals of the Government come to be discussed in Parliament the force of medical opinion will not be frittered away in suicidal bickering but be brought to bear, as common and collective arguments in respect of agreed principles. At the present moment the medical profession may be subdivided as follows: First there are some who think about the organization of the profession and some who do not, and the latter class is probably the larger, for the medical life is a very absorbing one, and the actualities of pathology are naturally more real to the busy practitioner than any schemes of reconstruction which may, or may not, take effect upon the occurrence of future legislation. It is depressing to think that only the smaller proportion of the medical profession as yet heeds the professional future. Then all that proportion of the medical profession which does heed the future is not in agreement as to the direction in which reform should come. There are three main divisions among them. First, there are those who consider that all the best work will always be done by individual doctors treating individual patients in accordance with any routine that suits the individual parties. Secondly, there are those who think that all medical service being a national asset, medicine should be administered by the State, and that all medical men, having obtained a diploma from the State, should *ipso facto* become State servants. Thirdly, there are those who think that, at any rate for the present, the truth lies somewhere between the two extremes, and who would like to devise a scheme whereby the State got a certain proportion of the services of all the medical profession as a right, while the doctors, as their right, would be able to reserve to themselves a certain amount of their time and their opportunities for individual work and profit. Englishmen are said to be especially fond of compromise, and certainly it is from this third class that the best schemes for the future development of the medical profession have emanated. These schemes have been many, and the last to attract attention was one laid down by Major-General Sir Bertrand Daw-

son in the Cavendish lecture recently delivered before the West London Medico-Chirurgical Society. Sir Bertrand Dawson's scheme would provide the public with State-subsidized hospital buildings and institutes to be distributed in accordance with geographical and population needs. All these hospitals, at the periphery of the scheme, would be served by the medical profession, who would be paid by those who could afford it and who would render aid to the others, partly paid or wholly gratuitous according as those patients were beneficiaries under the National Insurance Act or objects of medical charity. Then each of the district hospitals, general and special, and of all the various kinds, would be connected up with institutions at the largest center of population in the neighborhood, and from these consultant medical and surgical advice on all subjects would be drawn. This is, it will be seen, a working scheme whereby doctors do public work yet preserve individuality, and under which they are helped by the State exactly in the place where help is most needed, namely, by the provision of proper quarters in which to house poor patients, and proper premises in which to conduct medical research. The scheme gives general practitioners of every grade the chance of playing their part in the evolution of scientific medicine.

A case of great interest to the medical profession is now being heard before the King's Bench Division of the High Court of Justice, in which certain medical men, medical officers of an institution entitled the Coventry Medical Dispensary, are bringing an action for conspiracy, libel, and slander against the British Medical Association and the Coventry local officials thereof. The case is now proceeding, and has been opened at such length that there is no doubt the verdict will not be given before this letter is despatched, but there will be no question of contempt of court if I outline the case, as far as it has gone, because the actions of the British Medical Association are admitted—it is only the interpretation of them which is strenuously denied.

Many medical aid dispensaries have been mischievous to the proper administration of medical benefits to the public because of four main things: (1) the dispensary admits to the benefits of the club persons whose income is so high that they could very well afford to pay adequate fees to private practitioners; (2) the dispensary, by handbills or canvassers, advertises its medical staff to the detriment of other practitioners in the locality; (3) the dispensary pays its medical staff inadequate salaries; mainly because (4) the dispensary is under lay management, the medical voice or its executive being absent or outvoted, so that sums of money earned by the medical work of the staff are allocated to the payment of secretaries and canvassers. Under some or other of these counts the Coventry Medical Dispensary earned the disapproval of the British Medical Association, which, many years ago—at least ten—decided that members of the Association should not hold office at the dispensary, and should not meet professionally those who did so hold office. Certain medical officers of the dispensary consequently resigned their posts, but other medical men took their places in the face of notices in the *British Medical Journal* warning them not to engage themselves without inquiry into the constitution of the dispensary, whose advertisements were refused by the medical press. The action of the British Medical Association in this locality, confirmed by the central organization of the Association, led to certain events which furnished some of the medical officers of the dispensary with obvious grounds for legal action. Undoubtedly they were made to feel publicly that they had defaulted from professional standards, and they lost patients either from this reason, or because it became known that in the event of a consultant opinion being required in a difficult case, the opinion could not be obtained in the neighborhood, save where the question at issue was the saving of life.

The great question at issue before Mr. Justice McCardie, one of the strongest and most learned judges on the bench, has a most important bearing upon professional ethics in this country. I am saying nothing about the particular facts of this case; it would not be right to try to guess what view Mr. Justice McCardie, who is sitting without a jury, will take of the evidence that the dispensary has been managed to the detriment of the medical profession in the indicated ways; it would be equally wrong to suggest either that the damages alleged by the dispensary's doctors have not been incurred, or that the professional boycott of these doctors, has not been in accordance with general professional tenets. But whatever the result of the case may be, the medical profession will obtain an important ruling on the legitimacy of erecting an ethical tribunal within itself, and acting thereon. The General Medical Council has the ethical control of the medical profession as its statutory business by Act of Parliament; if this conduct of a medical man cannot be brought under the notice of the General Medical Council as having transgressed any laws or principles of that council, can no professional tribunal deal with him when his actions conflict with accepted professional standards? That is the great question at issue, and there is no doubt that the medical profession awaits Mr. Justice McCardie's decision with anxiety.

At the last meeting of the Council of the Royal College of Surgeons of England, Sir George Makins was re-elected President, and Sir John Bland-Sutton and Mr. W. F. Haslam were elected Vice-Presidents. Mr. Haslam, who is professor of surgery in the University of Birmingham, is among the most prominent provincial representatives on the Council of the College. Prominent among the new members of the Council is Mr. J. Lynn Thomas, the well-known consulting surgeon at Cardiff, so that the old reproach to the college that it is an entirely London affair is not holding good at the present moment.

Pneumonia and Bronchopneumonia in Nurslings from Descent into Cellars.—Netter and Triboulet call attention to a new consequence of air raids in the shape of dangerous respiratory affections as a result of taking babies to cellars at night. In the Trousseau Hospital 21 of the nurslings as a result of these experiences developed pneumonia or bronchopneumonia, with 7 deaths. Exposure was the sole causal factor.—*Le Progrès Médical.*

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

PRÉSIDENT POINCARÉ APPRECIATES Y. M. C. A.—RED CROSS RELIEF WORK IN ITALY—AN AMERICAN HOSPITAL TRAIN IN FRANCE.

PARIS, July 2, 1918.

DR. JOHN R. MOTT, of the American Y. M. C. A. war work council, has just returned from his tour of inspection among the American and French troops and has been received by President Poincaré. The President said to Dr. Mott that in his own name, in the name of the Government and the people, he wished to thank the American people for the indispensable service rendered by giving to the French Army the service of the Association. Dr. Mott has discussed with both M. Clemenceau and President Poincaré Y. M. C. A and Foyer du Soldat work. Both expressed first-hand knowledge of the work and unqualified approval of it. During his visit to the front and in the training areas Dr. Mott found scores of Association huts and "foyers" working in varying conditions, many under shell fire and some of the work actually being carried on in the front line. Both French and American generals bore testimony as to the military value of this agency and its service in promoting the comfort and well-being of officers and men.

Captain Charles Carroll of the American Red Cross and one of the founders of the American Ambulance, has just returned from a visit to Italy with the Italian Commission of the American Red Cross. He is convinced that Italy is fully alive to her responsibilities, is determined to drive the enemy out of her invaded provinces and will work heart and soul to help the Allies achieve their great aims. The Red Cross, realizing the suffering caused in Italy by the increased cost of living, decided to distribute a large sum for relief throughout the country. This distribution was undertaken by delegates sent to all parts of the country. Captain Carroll was on the Adriatic coast, where mine fields had cut off an important source of industry—the fisheries. The distress was marked, but this action of the American Red Cross not only cheered up the population, but gave it a practical demonstration of the value of America's entry into the war.

In addition to this special relief, the American Red Cross organized other work along the coast. At Rimini shoe factories were established for the refugees from Venetia as well as hospitals for children. At other coast towns, as well as in the interior, much assistance was given to local Italian charities that are in many cases admirably organized, but needed funds. At important railway junctions canteens have been established, and refugees and many soldiers are supplied with coffee and food by Red Cross workers. All along the coast the work of the American Red Cross is admirably handled, and the name of America is acclaimed with enthusiasm by all classes. At all the towns visited, demonstrations were organized, and speeches made lauding America as the representative of the principles of Liberty and Democracy. At Ricanati, a beautiful town on a high hill in the province of Macerata, windows were decked with flags and women threw flowers as the American Red Cross delegates were conducted to the municipal buildings.

When the full story of what has been done by the American Red Cross in its multitudinous activities is written it will prove to be one of the brightest pages in the history of this terrible war.

Great interest is evidenced by Americans and French alike in the American Hospital Train, now operating in France. This train stood on a siding awaiting orders, in a part of the country where Uncle Sam's hospital arrangements are on an enormous scale and magnificently complete. The train is about 930 feet long, and is composed of 16 carriages. These are fracture and infectious-ward wagons, staff, kitchen and four general ward wagons, pharmacy wagon and operating-room; then come five ward wagons, another kitchen and staff carriage and one for stores. A medical officer was asked to tell him how many things were lacking to make the train as complete as any ordinary hospital at home, and after reflecting he replied, "None."

This handsome hospital on wheels will accommodate 360 patients in cots. But it can carry 480 sitting down, and at the same time 120 in cots, making in this way accommodation for 600 patients. Each ward has 36 cots, hung in threes, one above the other. When desired, the top cot may be slung flat to the side of the wagon, the second cot slipped down and made a back to the lower cot, thus forming a sofa or lounge. The space between the rows of cots is very wide—sufficient to allow a stretcher to pass with ease. The train carries a water supply of 2,835 gallons, apart from the drinking water carried in filters. Electric fans change the air completely when the train is in motion. The heating is, when the engine is detached, entirely independent. There are bathrooms, douches, lavatories, drug stores, grocery and butcher supplies, and so complete is this provision department that 500 persons can be comfortably fed for three days at a stretch.

The staff comprises three medical officers, a manager, two lieutenants, a sergeant of the first class, two sergeants, two cooks and thirty-one enlisted men. The carriages are the last word in hygiene—rounded corners, so as to be easily cleaned, cheery, and extremely neat, all in white enamel, finished off in mahogany. These are only some of the details that catch the eye of a layman. But there are many others. These wagons are not turned out of American shops. It was found impossible to get results owing to transportation difficulties. So they were built in England, under American supervision. Major (Dr.) William Bertram Meister is in command of this train and he is very proud of his responsible post.

In passing through one of the kitchens, I noticed a cage of canaries, and they seemed wonderfully happy in their hospital home. "That," said the major, "is a little souvenir of one of our trips in France. We pulled up, one day, at an out-of-the-way siding, and awaited orders. While there a Frenchwoman came and implored us to save the life of her little daughter, who required an immediate operation. We could hardly refuse and were very glad to restore the little girl safe and sound to her mother. The poor woman was completely overcome with gratitude and, with tears in her eyes, emptied her savings in the hands of an astonished lieutenant. Of course, we gently assured her that we could accept no fees or gifts, and supposed we had got

rid of her when she left. Not a bit of it. That evening the woman came again, and, after leaving us this cage of sweet-singing canaries, fled in precipitation. We never saw her again. But those are *some* canaries, and we are mighty glad to have the cheery little songsters."

146, Avenue des Champs Elysées.

1. Modern Principles in the Control and Management of Cancer.—Edward Reynolds comments on the recent changes which have taken place in our knowledge of the malignant diseases, due in large measure to the work of the American Society for the Control of Cancer. He points out that all authorities are now agreed that there is no sharp line between the benign and the malignant and that many malignant new growths originate in, or about, originally benign growths or ulcers. In general, most benign new growths must be regarded as potentially malignant, though the lipomata, for instance, are almost invariably innocent. A malignant new growth is frequently the product of continuous chronic irritation, which results in hypertrophy of the normal tissues; this is followed by proliferation, then by the extension of the epithelial elements into the surrounding non-epithelial tissues, and the assumption by the individual cells of the malignant characteristics, in successive stages. (In the sarcomata, of course, the malignant process originates in connective tissue.) The essential change in our views is an acceptance of the modern idea that the duty of the physician to his patients is now to recognize, diagnose, and treat radically the conditions which ordinarily *precede* cancer and which for the most part are readily curable if radical treatment is adopted before actual malignancy has been established. In the digestive system and other difficult situations, diagnosis can be made only by the use of intricate and expensive methods of modern laboratory diagnosis at a time when symptoms warrant no more than a suspicion. The disease is not contagious and the influence of heredity is probably negligible. The general principle of treatment is the immediate removal of any mechanical or physiological irritation which could conceivably cause an existing thickening or ulceration, and if this removal is not followed by prompt disappearance of the lesion, an immediate and thorough excision of the induration or ulcer while still benign, by an incision made through unaffected tissues and without entering the lesion itself. Radiation and the use of the cautery should be avoided during the early stages though they are of great value in the palliation of advanced disease. The following are pre-cancerous conditions which are not malignant: moles (and especially pigmented moles), keratoses, ulcers of the skin and orifices of the body, gallstones, ulcers of the stomach, ulcers of the mouth, cystitis, erosions of the cervix, premature or obstructed involution of the breast, uterus, and prostate, the adenomata, the papillomata (especially in the intestines, bladder, and thyroid glands), cysts in the ovary and breast (because they tend to develop papillomata of their linings), polyps of the uterus or rectum, and, in general, all epithelial neoplasms. The dictum "*ubi tumor, ibi incisio (excisio)*" may be accepted as a safe general rule. Reynolds then proceeds to apply these principles to a few of the situations in which cancer most frequently occurs. He points out that in the case of squamous epitheliomata of the surface and carcinomata which originate in the follicles of the skin, radiation, cauterizing agents or freezing mixtures may be employed in the early stages; if any suspicion of malignancy arises, however, they should be radically removed together with the nearest set of lymphatic glands. It is important that all tissue removed should be examined under the microscope at the time of operation, and even when the immediate examination is negative the tissues should subsequently be carefully studied by a pathologist. The organs of the digestive system are among the most common seats of cancer, especially in men, and their inaccessibility makes early diagnosis extremely difficult. In cancer of the stomach the symptoms are those of chronic indigestion with, later, bloody vomitus, loss of weight, and change of color. In cancer of the colon the symptoms are persistent colic with bloody stools and, later, attacks of obstruction. Diagnosis is made by use of the *x*-ray after a barium meal and enema, and by exclusion of the ordinary sources of rectal bleeding through a proctoscopic examination. An exploratory abdominal incision should be done in doubtful cases. A positive diagnosis can rarely be made until the case is beyond the prospects of cure. In cancer of the rectum, a differential diagnosis between incipient cancer and hemorrhoids can be made only by physical examination with the finger and proctoscope. From the nature of the organ, operation, even in the early stages, is extensive. Cancer of the pancreas, liver, or gall bladder is rare, and is inoperable except when incipient cancer is discovered in the process of removing gallstones. Cancer of the breast is perhaps more controllable than in any other situation. Success depends upon early operation; any chronic lump in the breast which has persisted for a month without decrease should be removed. Cancer of the uterus may take one of two forms—the squamous carcinomata of the cervix and the adenocarcinomata of the body. With early and efficient treatment, prognosis is good in both cases. When actual malignancy is present permanent relief is rare in the first case. In adenocarcinomata of the uterus, prognosis after hysterectomy is favorable even in the presence of fully developed disease, so long as peritoneal perforation has not taken place. Reynolds closes with a few words on the palliation of inoperable cancer. Radiation should be employed in advanced disease of the cervix, prostate, and about the mouth and nose, also in Hodgkin's disease; it relieves pain and decreases hemorrhage and offensive discharges. The removal of sloughing portions of a superficial growth, either by the knife or by the knife and cautery, often decreases suffering. Ligature of a number of the nutrient arteries may also decrease the size of the growth. Tracheotomy, gastroenterostomy, and colotomy, neurotomies or deep infiltration of the plexi which supply the affected part, may all result in alleviation of symptoms.

2. The Successful Treatment of Chronic Pathogenic Infections of the Lower Respiratory Tract.—Irving Wilson Voorhees draws attention to chronic infections of the lower respiratory tract—the larynx, trachea, and bronchi—and the importance of combating the microorganisms which cause the infection. The organisms most commonly found are those of the streptococcus or staphylococcus family and the *Micrococcus catarrhalis*. Sputum should be obtained in all cases and cultures taken from the nose and throat whenever symptoms are referable to these organs. If deemed necessary a vaccine should be made from the culture and whenever possible the site of bacterial growth should be determined. A continuous desire to scrape the throat indicates the presence of mucus on the vocal cords. Plaques of mucopus, mucus, and blood streaks are often seen, particularly in cases where the *Streptococcus mucosus* is present. In chronic tracheitis the mucous membrane over both true and false cords is

often covered with crusts. There is a dry, hard cough which becomes easier when the crusts soften and can be coughed out. The secretion is viscid and when dried becomes firmly attached to the epithelium and on coming away leaves a raw, bleeding, eroded surface. The voice is husky and at times there is aphonia. The condition may be limited to the trachea or may extend into the larger bronchi. In one case a small encapsulated abscess cavity was found; culture showed a staphylococcus organism. In chronic bronchitis with copious, fetid discharge, the possibility of a foreign body in a bronchus must be considered. In all cases a careful history should be taken as to how the condition began, its probable origin, whether following pneumonia, grippe, etc., the question of associated disease of heart or kidneys, duration, local symptoms, character of cough and sputum, effect of climatic or barometric factors, former treatment, and so on. A thorough local examination of the nose and nasopharynx should be made for obstruction and presence of pus. The larynx and trachea must be studied with the laryngeal mirror, and if this method fails, with the direct speculum. A specimen of secretion should be secured in every case and submitted to bacteriological examination. X-ray examination of the nasal sinuses and of the chest is sometimes necessary, and a Wassermann may throw surprising light on a baffling problem. Physical signs are not of much value. Treatment should be directed toward improving the patient's general condition and destroying the bacterial parasite. Voorhees has used the vaccines with great success. Whenever possible he prefers the autogenous kind. He points out the importance of the mode of preparation of these vaccines; heating, for instance, may exert some lipoid change which renders the vaccine ineffectual. He comments on the fact that direct treatment to destroy the microorganisms has been sadly neglected. The silver preparations are especially helpful in case of crusting. Silver nitrate, however, should not be swabbed on with an applicator but sprayed directly into the trachea with a De Vilbiss anatomizer (No. 52) or dropped in the bronchi with a laryngeal syringe. Silvol, an analogue of silver nitrate, has been used with success and much is to be looked for from the new dichloramine-T of Carrel-Dakin. Too much importance cannot be attached to the necessity of persistent and repeated applications of bactericidal agents. Cultural conditions are ideal and bacteria grow at an enormous rate on the respiratory mucous membrane and, therefore, treatment should be administered at least once, and if possible twice, a day.

2. Nervous and Mental Symptoms in Exophthalmic Goiter.—Lewellys F. Barker points out that the intimate relationship of the endocrine glands and the nervous system is nowhere better illustrated than in the symptomatology of exophthalmic goiter, in which condition neuropathic and psychopathic phenomena predominate. Even in the disturbances looked upon as non-neural in origin, Barker suggests that a neural link may later be found. Although both the cerebrospinal nervous system and the vegetative or autonomic nervous system (including the sympathetic and autonomic systems) exhibit deviation from the normal, it is to the latter system that the larger number of pathologic-physiologic phenomena are referable. A consideration of the symptoms met with in exophthalmic goiter (of which a list is given) is in itself proof of this. These symptoms are never all found in the same case and some of them are opposites—epiphora and dry eyes, sialorrhea and xerostomia, constipation and diarrhea. The English physiologists, Gaskell and Langley, have shown that there is a double innervation in all autonomic domains. Normally there seems to be a fairly stable balance between the innervations of one set and those of the other set of fibers, each reciprocally antagonistic in their effects when stimulated, and this balance is temporarily and adequately upset from moment to moment by certain stimuli correspondent to physiologic needs. It is probable that, in some persons, constitutionally inferior, there may be a special sensitiveness to one set of innervations at the expense of the other; Eppinger and Hess have postulated the conception of vagotonia and sympathicotonia. In exophthalmic goiter a mixture of the phenomena of sympathetic stimulation in one domain with the phenomena of craniosacral autonomic stimulation in another is often met with; or the phenomena of either of these types may be predominant, *i.e.* the socalled sympathicotonic and vagotonic types of the disease. Though the facts are insufficient to warrant any dogmatic assertion regarding the pathogenesis of these symptoms, it is certain that their careful analysis and a consideration of their relation to one another have awakened a new interest in visceral neurology and bid fair to stimulate research. Toxi-degenerative processes involving the peripheral neurons (both motor and sensory) of the cerebrospinal nervous system are only met with occasionally, but do sometimes arise in exophthalmic goiter. In the domain of the cerebral nerves the nervus oculomotorius, the nervus trochlearis and the nervus abducens are most frequently involved. Isolated palsies of the nervus facialis are sometimes observed. Most interesting of all are the cases of palsy in the domain of several cerebral nerves, yielding the clinical picture of an acute, a subacute, or a chronic, bulbar paralysis. Further study is needed to decide the importance or unimportance of thymus hyperplasia in these cases. Barker states that what has surprised him most has been the constant presence of extensive evidence of disturbed function of the peripheral autonomic nerves in contrast with the apparent absence of evidence of disturbance of function of the peripheral cerebrospinal nerves. Of the grosser organic lesions of the brain and spinal cord occasionally encountered in exophthalmic goiter, none seems to stand in any direct relation to thyrotoxic cause. The neurotic and psychotic symptoms manifested in these cases are of particular interest, and Barker suggests that the nervousness and abnormal behavior of patients suffering from exophthalmic goiter may be due to abnormal functioning of the fundamental instinctive mechanism on which the whole personality depends. Each instinctive mechanism has a cognitive, an affective, and a conative component, involving a knowing, a feeling, and a striving. In exophthalmic goiter, it would seem as though the affective-conative processes were more involved than the cognitive. As yet it is impossible to say how far the nervous symptoms and especially the pathological emotivity of patients depend upon a direct intoxication of the brain itself and how far on indirect effects on the higher nervous apparatus through an intoxication of the vegetative nervous system or of all the body cells in which the ultimate metabolic processes go on. Barker, however, is inclined to lay more stress on injury to the lower and more primitive mechanisms.

1. The Goulstonian Lectures on Modern Views on Diabetes and on the Significance of Acidosis in Disease. Lecture III. Acidosis in Disease.—E. P. Poulton defines acidosis as an increase of acid relative to basic radicles in the blood, the CO_2 of the blood not being considered (Barcroft). It has nothing to do with the final reaction of the blood, *i.e.* its hydrogen ion concentration. The condition may be one of "compensated," "uncompensated," or "overcompensated" acidosis, the respiratory center being overactive in the third case. It has been shown that the effect of altitude results in a compensated acidosis, which may be considered as a process of acclimatization. In muscular exercise, on the other hand, the acidosis is uncompensated, and Barcroft has shown that this uncompensation is greater if the exercise is taken at an altitude. During pregnancy there is a fully compensated acidosis, but in severe cases of eclampsia the condition may resemble that found in uremia. Hasselbalch found that, as a general rule, an acid urine was accompanied by an increased ammonia excretion, and vice-versa. The increased formation of ammonia may be due to a specific formation of ammonia from protein, which spares the alkali reserve of the blood and prevents unnecessary excretion of phosphates. Emphasis has been laid on the fact that acidosis is accompanied by increased pulmonary ventilation and Yandell Henderson has attributed the condition of shock to acapnia. Cannon has found that there is an acidosis present; but there is no proof that the acidosis is the cause of shock. It may be a compensatory mechanism to guard against acapnia, but it is more probable that through failure in the circulation acid products are formed which produce the acidosis, and that it is the result of shock and not its cause. Poulton next considers heart disease and uremia. He points out that there are two distinct types of case—the uremic with the high blood urea and the case showing simple cardiac insufficiency. The uremic case tends to show acidosis in quite an early stage and this is compensated to start with; in the final stages the acidosis is uncompensated, and extremely acid values may be found. In the later stages of simple cardiac failure there is an uncompensated acidosis. The cardiorenal case is usually a mixture of these types. There is often obvious cardiac failure and the blood urea is raised to some extent. In the cardiorenal case there is often another independent condition—viz., the liability to Cheyne-Stokes respiration. This is due to a diminished excitability of the respiratory center, which is probably due to sclerosis of the arteries supplying the center, so that there is some failure in the supply of blood to the center. Wright and Fleming have published results indicating the existence of an acidosis in gas-gangrene patients and advocate injections of sodium bicarbonate as a therapeutic measure. The observations of Joffe and Poulton and the work of Bull, however, would seem to indicate that the acidosis was a terminal result of the infection and probably not of much significance; and it is possible that equally good results would have been obtained by intravenous injections of some neutral salt. Poulton adds, however, that in case of acidosis the most rational method, if an intravenous injection is assured, is to add some alkali to the fluid. In conclusion, he states that acidosis may be explained in two ways. It is either the result of increased production of acid, when the body uses the means at its disposal to compensate for its presence, and so prevent the rise in hydrogen-ion concentration of the blood; or acidosis is of itself of benefit to the organism and is deliberately produced by the organism by modifying the action of the kidneys and liver, *i.e.* the formation of ammonia and the excretion of alkali. These two types of acidosis will be similar to one another in the fall of the alveolar CO_2. They will differ in the character of the urine. In the one case the ammonia and the acidity will be increased and in the other both will be diminished. Acidosis may be expected whenever the ventilation of the lungs is increased, and it is difficult to believe its existence except to a minute extent when there is no altered respiration. It is a very common condition and seems to occur as a terminal phenomenon just before death, as has been shown, by Whitney. In such diseases as scurvy, skin diseases, and rickets, it is extremely unlikely that an acidosis exists. Finally, Poulton states that our knowledge of acidosis has been greatly increased during the past ten years, the modern conception of the condition being due before all others to Hasselbach of Copenhagen, Haldane of the Oxford, and Barcroft of the Cambridge schools.

3. The Sympathetic Nervous System and the "Irritable Heart of Soldiers."—Captain Francis Fraser and Lieutenant R. M. Wilson investigated a number of cases of "soldier's heart" in order to ascertain the mechanism by which certain of the symptoms manifested in such cases are produced, with a view to finding some therapeutic measure of relief. The cases investigated showed no signs of organic disease and included: (*a*) cases with a history of acute rheumatism or allied infections, even if some years before the onset of the symptoms of irritable heart; (*b*) cases with a history of an acute infection, such as typhoid fever, dysentery, influenza, trench fever, etc., or of "gassing" at a short period before the onset of the symptoms; and (*c*) cases with a history of shell shock or severe physical or mental stress immediately preceding the onset. The authors point out that these patients appear to differ from healthy men only in that a stimulus, such as excitement or emotion, produces an unusually large response. The symptoms by which the condition may be recognized—increase of pulse rate, shortness of breath, palpitation, precordial pain, and dizziness provoked by exertion or excitement—are associated with the organs of circulation and respiration, whose mechanism is related to the involuntary nervous system. Bearing this in mind, the authors considered that the following four drugs would probably modify the innervation of the heart, namely, adrenalin, apocodeine, acetyl-chlorine, and atropine; they, however, had opportunities of testing the reactions of the first two only. The intravenous method of administration was employed in all cases. Records of pulse rate and respiration were made with a Mackenzie ink polygraph, and of the systolic blood pressure by means of the Riva-Rocci type of sphygmomanometer and the auscultatory method of reading. Precautions were taken to avoid any reaction from excitement or exertion interfering with the effect of the drug. Controls were carefully chosen from men who had undergone the exertions of military service without

developing symptoms of "irritable heart." It was found that in the case of each of the two drugs—adrenalin and apocodeine—minute doses produced a greater action in the patients than in the controls. The authors conclude, therefore, that the sympathetic system of nerve fibers, using the term in its physiological rather than in its anatomical sense, is relatively unstable in that it appears to be more susceptible to the stimulating and depressing influences respectively of these drugs.

Berliner klinische Wochenschrift.

June 3, 1918.

A Clinical Study on Thymico-Lymphatic Status.—L. Mohr records three case histories in which a hypertrophied thymus produced compression of the trachea, the resulting disturbances being more or less marked. The symptoms met with may be due to all the endocrine glands and assume the most varied modalities. The writer places hypertrophy of the salivary and lacrymal glands and tonsil in the foreground. The diagnosis of hypertrophy of the thymus is made by palpation and percussion. Mohr believes that the gland can be percussed when it attains the weight of about twenty-five grams. Radiography may give a shadow over the aorta, the best incidence being from behind forward and from left to right.

Quinine as a Cardiac Medicament.—K. F. Wenckebach studies the practical indications for the use of quinine in cardiac conditions. The cardiodepressing action of the drug can be used to advantage in (1) auricular fibrillation, but the effect is only evident in recent cases; (2) in continued arrhythmia (delirium cordis) in which quinine may be given in combination with digitalis with excellent results. The writer advises the exhibition as follows: pulv. digital. jol. 0.5 to 0.8; quinine hydrochlor. 0.4 to 0.8; strychnine sulph. 0.002 to 0.003. To be taken in divided doses in 24 hours. The effect is obtained in three days, being made manifest by a notable slowing down of the cardiac action, which should not fall below 80 beats. The paroxysms may occur, but give in to smaller doses than were first exhibited. In hyperkinesis, such as paroxystic tachycardia, extrasystolia, etc., an intravenous injection of quinine, 0.75 may have an immediate effect. Basedow's disease is favorably influenced by a decrease in the force of cardiac contraction. The use of digitalis in valvular cardiopathies, chronic nephritis, and scleroses may trouble the patient from the force of the beats. Here, again, quinine can be used as a cardiac moderator with good effects.

May 21, 1918.

An Artificial Hand.—Von Balyer describes an articulated hand attached to an arm prothesis. The joint of the hand is connected with a joint of the thumb in such a way that extension of the hand produces an outward movement of the thumb. All that is necessary is to press the hand on its palmar aspect to cause abduction of the thumb. As soon as the pressure is relieved adduction takes place. This principle allows the wearer of the artificial hand to seize coin laid on a table, to take matches from a box, and other small objects.

Preventive Vaccination of Cholera.—H. E. Kersten believes that vaccination may render the beginning of a cholera epidemic both atypical and difficult to recognize. It is particularly prone to result in a febrile début which is relatively less frequent in subjects who have not been vaccinated. Mixed infection is much more common than is generally admitted. Kersten has noted that the effect of the vaccination does not last for more than five months, so that it should be repeated before the lapse of five months. He is of the opinion that at the beginning of an epidemic subjects formerly vaccinated may be again vaccinated even when they already show the early symptoms of cholera. There need be no fear of setting up a negative phase. Quite on the contrary, revaccination has seemed to give very happy therapeutic results.

Elimination of Coloring Matter by the Urine in Certain Renal Affections.—W. Stepp insists on the incapacity of the kidney, the seat of Bright's disease, to eliminate substances which give to the urine its normal color. The examinations made by Stepp indicate that urochrome is retained to a marked degree in these cases. The relation of this substance to the oxyprotein acids should draw one's attention to the possible etiological part played by these products of albumin disintegration in the uremic states, so-called. The amount of neutral sulphur eliminated may serve to measure these substances.

Deutsche medizinische Wochenschrift.

May 23, 1918.

Experimental Typhus Injection.—Ritz gives the results of his experiments which represent an important contribution to this much mooted question. Inoculation of guinea pigs with the blood taken from patients dead from typhus fever gave an incalculable disease in series, so that these results confirm the work of Nicolle, Conor, and Conseil in 1911. In no one instance would the condition of the animals be looked upon as an anaphylactic state or serum disease. Ritz was dealing with a true typhus fever because histological examination revealed the vascular changes belonging to this disease. Successive injections in the same guinea pig gave rise to a certain immunity conferred by the first injection. The writer tried to utilize his material to settle the question of the morbid etiology. He was only able to note that the serum of the animals acquired agglutinating properties toward the X 19 organism, in contrast to what takes place in man (Weil-Felix reaction). On the other hand the injection of X 19 produced a rapid agglutination of this proteus with the serum of the guinea pig. From these researches, it would seem to result that Friedberger's opinion that the X 19 is the causal agent of typhus fever is most improbable. It is impossible to maintain that in man there is either a para-agglutination or a mixed infection.

Hysterical Neuritis.—A. Bittorf believes that this process occurs as a secondary toxi-infectious inflammation since it commences after acute intestinal phenomena. Sensitive disturbances are more marked than motor disturbances. Paresis, pain, and anesthesia are manifest. The writer refers to a peculiarity belonging to certain cases, namely, an *ascensional début* and an *ascensional recovery*, this being contrary to what is observed in other types of neuritis. Treatment consists of heat, abundant feeding, and an energetic treatment of the intestinal process.

Wiener medizinische Wochenschrift.

June 8, 1918.

Hunger Edema.—R. von Jaksch gives some statistics of an official nature relative to this process, which is to be attributed to insufficient feeding. It has already been described during the Napoleonic wars and during the great Irish famine in 1835. German Bohemia has been the part of Austria most afflicted by this affection, the industrial districts being far more seriously hit than the agricultural regions. In 1917, 22,842 cases were reported with 1,028 deaths; the global mortality thus being 4.5 per cent. The mortality has reached 5.22 per cent. in the manufacturing districts. At the beginning it was thought that the disease was an epidemic as the first cases observed were in prisoner's camps. From the quantitative point of view, the affection is practically fatal with a minimum feeding of 1,400 calories daily for a person at rest (the writer estimates at from 900 to 1,000 calories the ration of the populations where the affection raged). The quality of the men also plays an important part. The Serbian prisoners suffered much less than the Russians although they received the same number of calories, which shows that potatoes did not replace the corn in nourishment to which the Russians were accustomed. The cardinal symptoms were bradycardia, hydropsy, polyuria and general lability. The edema, the most frequent symptom, may be absent in some cases. Blood examination revealed a decrease of the albumins and an increase of chlorides. The albumin may fall to 3 per cent. (9 per cent. being normal). Hypothermy may attain the point of eryesthesia and gangrene. The treatment is deducted from the pathogenesis of the process. The State should furnish a daily ration of 1,400 calories

for a medium-sized adult; for one engaged in light work 1,935 calories, and for those engaged in heavy work 2,365 calories.

The Development of Babies During the War.—L. Pollak points out that statistics show that the condition of nursing infants has become steadily worse from 1913 to 1917. The mortality has gone from 4.27 per cent. to 15.74 per cent. at the Prague clinic.

Correspondenz-Blatt für Schweizer Aerzte.

April 13, 1918.

New Sign of Spasticity of Organic Origin.—Bing describes what he terms the paradoxic ankle reflex found by him only in spasticity of organic origin and not obtainable in 200 controls of all kinds, including cases of functional spasticity. Thus far he has had 14 positive results in 19 cases of organic spasticity, in but 10 of which a Babinski was elicited. The underlying conditions comprised cerebral lues and meningomyelitis, cerebral embolism, multiple sclerosis, epidemic cerebrospinal meningitis (sequelæ), and cerebral traumatisms. To obtain the reflex the patient lies supine in the position for obtaining the ankle clonus—medium flexion at the hip and knee joints. The foot is flexed slightly on the leg so that the tendo Achillis is slightly taut. With a reflex hammer which is broad and heavy, the ankle joint line is struck anywhere between the malleoli. In positive cases a strong twitch occurs in the gastrocnemius while the foot makes a flexion movement as in the ordinary Achilles reflex. This behavior inverts that hitherto noted, for striking the anterior tendons is usually alleged to cause no motor phenomenon in injuries of the pyramidal tracts, save perhaps plantar flexion of the toes.

Operative Cure of a Cancer at the Esophago-Cardiac Juncture.—Bircher reports the case of a woman who has survived removal of a cancer in this locality for 18 months and is still free from recurrence. The intervention was entirely abdominal. There was marked gastroptosis, and as the tumor was not adherent resection was performed without much trouble. The esophagus stump was sutured and drawn through the stomach wound, to which it was united. A gastrostomy was then performed and the patient nourished through it for 10 days. The passage of a sound *per os* through the cardia at first encountered much resistance and one of 10 mm. only could pass. Nevertheless, patient gained 30 pounds. The resected portion measured 8 cm., three of which belonged to the esophagus. According to Witzel, as much as 14 cm. of esophagus may be mobilized through the diaphragm. The author thinks that from 4 to 7 cm. is the length realizable in surgical work. The establishment of an anastomosis between the esophagus and stomach requires great care, for the line of union must be fully covered by peritoneum to prevent infection. The implantation of the stump in the stomach is effected by fistula technique. In addition to the case already described the author has since operated on two others of the same character by the same technique.

La Presse Médicale.

April 25, 1918.

Renal Elimination, Normal and Pathological.—Ambard makes three types of elimination, viz., effraction, diffusion, and secretion. The former is not physiological but due to traumatism—rupture of the capillaries of the parenchyma leads to escape of blood into the urinary conduits with clinical hematuria and albuminuria. In these cases the degree of the latter may show great variation, sometimes only in proportion to the escaped blood, sometimes much greater. Elimination by diffusion may have to do with solutions or suspensions. It is believed that the monatomic alcohols, chloroform, and other substances leave the blood through diffusion, as if the kidney were an inert membrane. In other words, the kidney does not dilute or concentrate them. Glycerin, a triatomic alcohol, on the other hand, does not appear to be diffused. It looks at present as if the diffusible group corresponds with the oil solvents. Elimination by secretion is by far the most important, for urea, sugar, ammonia, chlorides, sulphates, and most of the drugs are eliminated in that manner. Secretion involves the law of ureo-secretory constants, or otherwise stated the act of concentration, *i.e.* the substance appears in the urine in a higher concentration than was present in the blood. The relationship between these two concentrations is constant for each substance. The principle is not universal, for sodium chloride and glucose, for reasons readily intelligible, do not exhibit any constancy of elimination. Glucose never escapes into the urine until it exceeds a blood concentration of 3 per 1,000 its threshold value. Hence the excess over the latter is the true blood concentration for calculations. In like manner the threshold of sodium chloride is 5.80 per 1,000. If the excess is .20, then .20 per 1,000 is the figure which enters into the secretory constant. In theory urea should have a threshold, but as a matter of fact it is not an integral part of the blood. If we happen to find 0.35 parts in 1,000 parts of blood this must all be counted as excess. The same is true of all substances other than native constituents of the blood present in fixed values. Secretion then deals with thresholds and ureo-secretory constants. If the constant of urea is 0.09 we shall find that iodine or other foreign substance exhibits the same constant. For functional testing we should use substances which have no threshold; and if we test the same kidneys with methylene blue, iodine, phthalein or what not the response should always be the same. The study of thresholds is far more complicated for these have only average values, maxima and minima being determinable. We may speak of 5.80 per 1,000 as the threshold for NaCl but 5.80 is really the superior limit, 5.60 being the lower limit. This mobility or plasticity of the threshold may be utilized in kidney testing, for phloridzin lowers the threshold of glucose in causing glycosuria while theobromine lowers the threshold of sodium chloride by causing chloruia, *i.e.* if there be chlorine retention. The subject of secretory constants leads us to the determination of blood urea in its relationship to uremia. If the urea maintains 2 per 1,000 concentration for a long period such a figure is incompatible with life and there is nothing gained by ascertaining the particular figure. But in concentrations below 2 per 1,000 there is not the same degree of fatality and the prognosis may vary with the exact concentration. The author fixes 0.50 per 1,000 as the normal maximum. If the concentration is from 0.50 to 1.00 per 1,000 there is disturbed function of the kidneys, he says, to the extent of 40 to 90 per cent. If the concentration is over 1.00 per 1,000 Ambard holds that the kidneys are from at least 80 to 98 per cent. insufficient at the time.

Hygiea.

March 30, 1918.

Nasal Reflex Neuroses.—Hofvendahl refers to the prodromes of reflex bronchial asthma—stopping up of the nose, sneezing, watery discharge shortly before the paroxysm—which suggest that nervous coryza and hay fever are reactions of the same type, although of different degrees. When the syndrome appears in bronchial asthma one thinks of a parasympathetic hyperirritation, as evidenced in the blood picture of eosinophilia. The same is seen in hay fever. Even in nervous catarrh with normal blood picture there is a certain tendency in the same direction. The abundant watery discharge suggests a hyperirritation of the parasympathetic, while the swelling of the turbinals, a phenomenon of vasodilatation, is affiliated. This syndrome is benefited for the time by atropine, which is known to paralyze the parasympathetic. In 3 cases related by the author tuberculosis was probably the eliciting factor through the action of its toxin which is known to exert a selective action on the parasympathetic. It is possible that tuberculous foci exerted mechanical irritation on the vagus fibers of the parasympathetic. Again, there may have been a congenital lability of the nervous mechanism. Pollen granules may have been active in some of the cases. The author found in the Hospital for Tuberculous about 10 per cent. of the patients suffering from so-called nervous coryza and as a rule this condition had preceded the first signs of the pulmonary lesion by an interval of several years.

Book Reviews.

THE DIAGNOSIS AND TREATMENT OF HEART DISEASE. Practical Points for Students and Practitioners. By E. M. BROCKBANK, M.D. (Vict.), F.R.C.P. Hon. Physician Royal Infirmary Manchester, Clinical Lecturer on Diseases of the Heart, Dean of Clinical Instruction, University of Manchester. Third Edition, with Illustrations. Price, $1.50. New York: Paul B. Hocher, 1917.

THIS practical little book on the elements of cardiac auscultation is a clear and concise description of how to diagnose heart sounds and murmurs with regard to their causation and differentiation. In the third edition a number of additional clinical points have been incorporated and a new chapter has been added on the general physical signs and symptoms of heart disease. The book is adequately illustrated and that it has proved useful to students is shown by the fact that it has gone through three editions since 1916.

A CLINICAL MANUAL OF MENTAL DISEASES. By FRANCIS X. DERCUM, A.M., M.D., Ph.D., Professor of Nervous and Mental Diseases, Jefferson Medical College, Philadelphia; Consulting Neurologist to the Philadelphia General Hospital; Ex-President of the American Neurological Association, of the Philadelphia Neurological Society, and of the Philadelphia Psychiatric Society; Foreign Corresponding Member of the Neurological Society of Paris and of the Psychiatric and Neurological Society of Vienna; Member of the Royal Medical Society of Budapest, etc., etc. Second Edition, Revised. Price, $3.50 net. Philadelphia and London: W. B. Saunders Co., 1917.

THE title of this book is an excellent description of it. In a clinical psychiatry of the descriptive type, little space and scant respect are found for the newer trends in the study of mental disease which look on the individual as a biological mechanism which may develop faulty adaptations to its environment, either through actual physical disease or through psychic maladjustments and failure to progress along the path of evolution. The stage in psychiatry which this book represents may be estimated by the opening sentences of Chapter II: "Pathology has as yet so little to offer that we must content ourselves with a purely clinical interpretation of insanity. A clinical interpretation is not only of practical value, but it is also interesting and scientific." To be sure, Dr. Dercum has a chapter on "The Psychologic Interpretation of the Symptoms," in which he very surprisingly borrows many of the doctrines of the psychoanalytic school, perhaps unconsciously. This chapter, by the way, would probably be more valuable included in the introductory chapter, in order that the practitioner might orient himself somewhat as to the meaning of symptoms before proceeding to study types of mental disorder.

The chief fault of the book is found in the chapter on the neurasthenic-neuropathic disorders, where the author speaks of "Insanity of the Special Fears," "Insanity of Indecision," "Insanity of Deficient Inhibition" and "Insanity of Deficient Will." This is neither a scientific nosology nor a useful one.

There are, however, many good points about this work. The descriptive pictures of mental disease are excellent and we do not see how a practitioner can fail to learn much from them. Then, too, the chapter on treatment is to be praised highly. After all, the question of treatment is the one which the physician is called upon to solve first of all in a majority of the mental cases he sees. Dr. Dercum has some good ideas about prophylaxis, but does not give the subject enough space; his advocacy of sterilization, too, is stated without sufficient explanation. His description of the extramural treatment of the individual patient is, however, above criticism. His discussion of delirium and its management is extremely valuable. Many practical points in the handling of mental patients are given, as, *e. g.*, the scheme for alternating nurses in cases of melancholia.

On the whole, we find much to praise and much to blame in this book. The beginner in psychiatry will learn a great deal from it, but we cannot recommend his following it too implicitly as he pursues the subject further.

PLAIES DU PIED ET DU COU-DE-PIED PAR PROJECTILES DE GUERRE. Par É. QUÉNU, Membre de l'Académie de Science et de l'Académie de Médecine. Professeur de Clinique Chirurgicale à la Faculté de Médecine de Paris. Avec 477 gravures et radiographies dans le texte. Prix, 16 Francs 50. Paris: Librairie Félix Alcan, 1918.

THIS volume of 460 pages contains the very large number of 302 case histories, with not much attempt at coordination and analysis. It is difficult to understand how a work of this size could have been written by one so situated as its author must be on any other plan. The cases and pictures tell the story. At the same time there are many solid pages of text. The foot is divided into the anterior and posterior segments and the ankle joint, each of which is considered separately when possible. The chapters cover pathology, symptoms, primary and secondary treatment, remote results of lesions, and remote results of mutilating operations—resections and amputations. The volume constitutes an exhaustive reference monograph on the subject of gunshot wounds of the foot and ankle.

LA GANGRENE GAZEUSE. Par ANDRÉ CHALIER, Ancien Chef de Clinique Chirurgicale à la Faculté de Lyon, Lauréat de l'Académie de Médecine, Médecin-Majeur de 2e Classe aux Armées, et JOSEPH CHALIER, Ancien Chef de Clinique Médicale à la Faculté de Lyon, Aide-Majeur de 1ere Classe aux Armées. Octavo of 388 Pages, with 52 Illustrations. Price, 8 Francs 80. Paris: Librairie Félix Alcan, 1917.

THIS book, written in collaboration by a physician and a surgeon, gives a very complete description of all phases of gas gangrene, the methods of treatment that have been found most efficacious and the results that may be expected under various conditions. All this is based upon actual experience during three years of war, upon statistics of 108 personal cases, details of all of which are recited in connection with appropriate portions of the text, and upon a discriminating review of the literature of this subject.

After a very interesting introduction dealing with historical and other general phases of the subject, etiology, pathologic anatomy, bacteriology and pathogeny are discussed, in order, thus building a foundation for the consideration of the clinical side of the subject. This is taken up in great detail under the captions: General symptomatology, clinical forms, associated morbid conditions and complications. Separate chapters are also devoted to diagnosis, prognosis, prophylaxis, and treatment.

While it is true that cases of gas gangrene are far less numerous now than at the beginning of the war, it is only because the principles involved in the avoidance or successful treatment of this type of infection have become well understood by those who have had experience in handling war wounds during the past three and a half years, and because the newcomers in the medical ranks have been able to profit by their experience. The subject is admirably covered in this book, and any American surgeon who can read French will be well repaid for the expenditure of time requisite for its perusal. He will then find himself much better equipped both to prevent the onset of gas gangrene, when the case is seen early enough, and to handle such cases when they do occur.

TYPHOID FEVER CONSIDERED AS A PROBLEM OF SCIENTIFIC MEDICINE. By FREDERICK P. GAY, Professor of Pathology in the University of California. Price, $2.50. New York: The Macmillan Company, 1918.

TYPHOID fever has been considered from many aspects, and especially from the clinical standpoints and the laboratory and public health points of view. Dr. Gay's endeavor in this work has been to deal historically with the development and present status of our knowledge concerning the mechanism of the disease. In accordance with this intention, the life history of the typhoid bacillus has been followed rather than the manifestations of the disease it produces. As a scientific consideration of the typhoid fever problem the work is highly elucidating.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Nineteenth Annual Meeting, Held at Richmond, Va., June 7 and 8, 1918.

DR. W. WAYNE BABCOCK OF PHILADELPHIA, IN THE CHAIR.

First Day—Friday, June 7.

Obituary of Jacob Friedman, M.D.—Dr. ERNEST ZUEBLIN of Cincinnati read the following: Dr. Jacob Friedman was born in St. Louis in April, 1856, where he received his primary education in the public schools, graduating from the High School in 1873. After successful studies at the Washington University from 1873 to 1876 he obtained the degree of Chemist from the same institution. In order to pursue his studies successfully Dr. Friedman taught in night school, so supporting himself throughout his academic course. In 1878 the St. Louis Medical College conferred upon the young promising scientist the degree of M.D. While interne at the St. Louis City Hospital and as resident physician in the Quarantine Hospital, Dr. Friedman, by his skill and courage, distinguished himself during the great yellow fever epidemic. This achievement deserves the recognition of the profession since the danger of becoming a victim of that deadly disease was no reason for the young doctor to shrink away from the great responsibilities of such a position. Dr. Friedman's career as teacher is very interesting. As the years passed by we see him steadily advance to higher and more important positions. In 1879 Dr. Friedman was appointed Demonstrator in Chemistry in the St. Louis Medical College and in the Washington University. In 1884 he became Adjunct Professor of Chemistry, which position he successfully filled until 1892 when he was appointed Professor of Chemistry in the Beaumont Hospital Medical College. After the consolidation of that institution with the Marion Sims College of Medicine under the new name of the St. Louis University School of Medicine, Dr. Friedman remained in the same position until 1904 when the same institution was anxious to have him as Professor of Therapeutics. Not only along the line of teaching and in Science were Dr. Friedman's qualities highly appreciated; in charge of the Medical Service of the Alexian Brothers his professional services were in great demand from 1897 to 1903. From 1902 to the time of his unexpected death, Dr. Friedman was Physician in Chief of the Jewish Hospital of St. Louis. Although Dr. Friedman as a citizen of St. Louis devoted most of his work and services to his native city, by his extensive travels in Europe and by his keen interest in medical science he added a great deal to his skill and medical knowledge. Devoted to his profession, to his patients, a man of the highest character, it was not surprising that in the course of his work he acquired a great following. Beloved by his patients, noted and well known for his patriotism and enthusiasm, well appreciated in his great integrity, his bluff honesty found a devoted following among the profession.

The above notes are only a short review of Dr. Friedman's work which will be remembered among his colleagues and friends. A successful, rich life has come to an unexpected and too early stop, and while we, the members of the American Therapeutic Society, pay our full admiration to the deceased member whom we will miss in our gatherings, we feel with the wife and family of Dr. Friedman the great loss of his death. The remembrance of him as a colleague, physician, teacher and friend will, however, remain as a stimulating example for those who are left of the ethical heights to which a noble profession may lead.

Obituary of Heinrich Stern, M.D.—Dr. THOMAS F. REILLY of New York read the following: Heinrich Stern was born near Frankfort, Germany, 50 years ago. Because his father had been bold enough to oppose the Prussianization of his native state, he was taught the meaning of *Schrechlichkeit*. As soon as his sons were able to travel the father literally drove them from the land of the oppressor, so that they might not experience a fate like unto his own. Soon after arriving in this country, Dr. Stern began the study of medicine. He received his first medical degree 24 years ago. A few years later he took a second degree. After some years in general practice he began to devote himself to a study of the diseases of metabolism. The prize offered by the New York County Medical Society for the best essay on "diabetes" was won by him and this brought him to the notice of the profession. From that time his work was consistently in the field of internal medicine.

He was connected either as founder or member with the following organizations: The Institute for Medical Diagnosis, and Philantropen Hospital; Visiting Physician, St. Mark's Hospital; Consulting Physician, Central Islip and Seney Hospitals; Sometime Professor of Clinical Medicine, at the German West Side Post Graduate Medical School; Lecturer on Medicine, Boston University; Founder and Editor of the *Archives of Diagnosis;* Founder of the Manhattan Medical Society and of the American College of Physicians, which was the culmination of a life-long dream. In addition he was a member of a dozen other medical societies. He was the author of upwards of 300 medical articles and of half a dozen text books on medicine, most of which were devoted to treatment in its various phases.

Dr. Stern's life was marked by unabated industry both in the line of original studies and the self-imposed exactions of his profession. He was an omnivorous reader with a most tenacious memory. Time and again he made a lasting impression on his fellows by quoting extensively from an article written by a friend, maybap a decade or two previously and mostly forgotten. He was a strong character; positive in his likes and dislikes; honest in his purpose and often misunderstood. The fatal illness which hung as a shadow over Dr. Stern ever since about the time of his election to this society, prevented his active participation in its deliberations but his interest remained to the end and its aims and purposes were always uppermost in his mind.

Address of Welcome.—Dr. BEVERLEY R. TUCKER of Richmond, Va., said that Richmond possessed many historical associations. It was near here that the Indian maiden, Pocahontas, saved the life of Captain John Smith, when he came here to seek supplies for the early settlers who were starving in the Jamestown colony. Here Nathaniel Bacon had his quarters, and from here this leader sallied forth to strike the first blow for American liberty against the tyranny of the English crown. Here Patrick Henry made his speech for American liberty which rang around the world. The government of the confederacy was situated in this city. Coming on to later times one found men no less deserving of fame. The late Dr. George Ben Johnston was the chief spirit in building up and equipping the medical College of Virginia. Three present hospitals were organized by him. His wonderful personality tended to elevate the ideals of the profession and his influence spread through this whole section and into all the Southern states. He stood for all that was fine and true and high in medicine and his life would remain an enduring influence for those principles. Fifty years ago the battlefields around Richmond were soaked with the blood of brothers fighting for the principles of civil life. To-day, their sons were fighting for the common cause of humanity so that the principles of freedom might live and have breathing space upon the face of the globe. The American Therapeutic Society, meeting here to-day, had two duties to perform: first, the inauguration of a method of combating the terrible spread of disease that was the scourge of every war; second, to aid the people at home by keeping up the highest standards of this scientific association. With these ends in view they had come together to-day. The City of Richmond extended to this society, individually and collectively, the welcome of the profession and also all the social welcome that such a community could afford.

Response to the Address of Welcome.—Dr. R. T. MORRIS of New York said that the old ideal of character was to combine utility with piety. This society aimed to combine science with good fellowship. The

spirit of American social life was very apparent in Richmond. There was a thinning of the ranks of the society on this occasion. This was due to high idealism. It was because the country as a whole was engaged in a fight for the supremacy of idealism over materialism that the membership was so depleted. As a whole the members of this society had shown their willingness to stand in the forefront of the fight. The welcome extended to them by the members of the profession at Richmond had made them feel quite at home.

Operative Measures in Duodenal Ulcer.—Dr. GEORGE REESE SATTERLEE of New York read this paper. (See page 265.)

Treatment of Intestinal Stasis by Duodenal Lavage.—Dr. CHARLES D. AARON of Detroit presented this communication. (See page 268.)

The Ambulatory Treatment of Duodenal Ulcer.—Dr. ELMER B. FREEMAN of Baltimore, Md., presented this topic. One hundred and sixty-nine cases at the Johns Hopkins Hospital Dispensary were studied and treated. Those with pyloric obstruction were excluded and referred for surgical treatment. The age of the patients was from 17 to 68 years, early ages predominating. More cases were noted in the male sex. In negroes it was very infrequent. Pyorrhea was an accompanying symptom in all cases. Alcoholism was present in 25 per cent. The use of tobacco, tea, or coffee was frequent. Appendicitis was present in 7 cases. Typhoid fever occurred more frequently in the past history than any other disease. The symptom of pain and tenderness in the upper right side of the abdomen was present in all but 4 cases. Bowels usually showed a tendency towards constipation. There was hyperchlorhydria in 26 cases; normal acidity in 54 cases; subacidity in 26 cases. Fluoroscopic examination was made in all cases with the patient in a standing position. Hypermotility of the stomach was marked in all cases. Occult blood was found in the stools in 100 cases. Treatment was by removal of infectious conditions in the mouth; regulation of habits; regulated diet; hot moist applications made over the abdomen; medication. The latter consisted of large doses of belladonna, beginning with 3 and increasing to 20 or 30 drops 3 times a day. This lessened secretion, muscular spasm, and pain. Alkalis were used, viz., sulphate of magnesia and subcarbonate of bismuth. This treatment was of no value in cases of obstruction, but in cases where it was necessary for the patient to keep on at his work a good deal could be claimed for the treatment.

Dr. ERNEST ZUEBLIN of Cincinnati, O., said these papers covered the subject from the diagnostic and therapeutic standpoints. It was necessary to be more than careful in diagnosis. Duodenal ulcer meant a series of examinations which were usually most disagreeable to the patient. In regard to the duodenal contents examination by the Einhorn tube and the string test might be valuable. Objection was frequently made to the string test, but this might not be so much the fault of the method used as of the interpretation of the result. The string and bucket should be swallowed in the evening and withdrawn the following morning. If the blood stain was in the yellow bile-stained portion close to the attachment of the duodenal bucket, there was strong probability of a duodenal ulcer. As to the toxemia, the catabolism of the proteins might be interfered with by faulty digestion and the general organism might suffer by faulty absorption, or there might be a kind of anaphylaxis with symptoms reflecting on the other organisms which were falsely interpreted. In regard to lavage, Dr. Aaron last year had made observations on the effect of duodenal lavage in lowering high blood pressure. He would like to know more about the histories of these cases. The statistics of Dr. Freeman were very valuable as showing what could be done in the treatment of ambulatory cases. The medical treatment of this condition could not be exclusively medical, one had to defer to the surgeon in many instances; at the same time, operations were often needlessly performed. Physiological tests were necessary to complete the diagnosis. As regarded belladonna, it was probably necessary to employ heroic doses, but did the patients not complain of eye symptoms or other toxic symptoms? It was no doubt necessary to choose the lesser evil, but it would be surprising if there was no intolerance.

Dr. DOUGLAS VANDER HOOF of Richmond, Va., said that good team work was necessary between the internist and the surgeon. It had been his practice for 12 years to have a consultation with a surgeon about these patients with duodenal ulcer. He did not do this so frequently as formerly. The doctor was apt to formulate in his own mind the procedure of choice. The question of age entered into this matter. After 40 years of age medical treatment was advocated rather than surgical. The situation of the ulcer was likewise considered. One felt particularly unhappy about ulcers situated near the pylorus because of the possibility of malignant disease. Ulcers in the duodenum were the easiest thing to diagnose clinically. Competent *x*-ray diagnosis should be sought. In regard to treatment a plan of simple routine was of most use. Many features had been discussed that morning, but a few should be emphasized. One thing was frequent feeding. These patients must be fed 6 times a day. They should never go without feeding every three hours, even if the church or the house was burning down. This was not for a month or two, but for 18 months, and not omitted a single day. It was possible to undo in 2 days all the good of two months. Cooperation of the patient was essential. If pain occurred a glass of milk should be taken. This could be done 5 times a day. One intelligent patient, a man of 70, had had occasion to take milk 5 times during the night. He had continued to follow this treatment of frequent feeding and taking milk and had had no return of symptoms for 5 years. Olive oil taken alone as the first course of a meal, or a cup of cream 3 times a day before meals, was a useful measure. After meals bismuth nitrate, 3 parts, and calcined magnesia, 1 part, were used. In regard to diet, these patients should not be restricted as in general they had too much digestion. Acids and acid fruits were forbidden, as were soups, meat extractives, and alcohol, and tobacco. Seasonings, such as salt, Worcestershire sauce, etc., were to be avoided; intense sweets like honey and molasses were harmful. There was no restriction of meat or of starches. These means would afford great relief and a clinical cure. The only objection to medical treatment was that one was apt to overlook associated lesions in the abdomen. The great advantage of surgery was the opportunity for complete exploration. Cases that failed to yield to medical treatment were no doubt associated with appendix or gall bladder conditions. It was interesting to hear about the doses of belladonna which the patients had tolerated. He had tried to run belladonna up, but the patients complained bitterly of disturbance of vision. It was possible that the dispensary patient did not use the eyes so much. In complicated duodenal ulcer cases the patient should be carefully watched and if he did not do well, a surgical consultation should be asked for. Medical treatment should not be persisted in unless the patient got well.

Dr. JACOB DINER of New York said that he was interested in what Dr. Aaron had said about magnesium sulphate. This drug was very interesting. It was supposed to be passed out through the gastrointestinal tract and from the bowel. As a matter of fact it was found to be reabsorbed by the colon and excreted by way of the kidneys and had a stimulating effect on the renal epithelium. Its disagreeable taste was one objection to its use. It could, however, be made very palatable by the addition of aromatic sulphuric acid (two per cent.), and sweetened with glycerin. With reference to bismuth, he believed that in peptic ulcer it was indicated because it acted as a demulcent just as milk did, upon the mucous membrane. Olive oil had the same effect. Bismuth subnitrate, used internally, was readily broken up and liberated nitric acid. This was irritating. Bismuth oxide could be used instead of milk of magnesia. He expected to hear Dr. Aaron speak of the effect of exercise on stasis. Most of the people followed a sedentary occupation and the stasis was more or less due to that. Gradually increasing exercises, combined with doses of magnesium sulphate which cleared out the intestinal tract, would overcome the condition.

Dr. Thomas F. Reilly of New York said that Dr. Freeman said he could diagnose these cases by the hypermotility, but in the fluoroscopic examination it could be shown that any drag on the intestinal tract produced hypermotility. How could he rule out gall-bladder conditions, from the hypermotility due to ulcer? These patients often presented a peculiar pallor which was of some assistance in the diagnosis. A large percentage of these cases also had a positive Wassermann. A Wassermann should be done in all cases. In regard to the occurrence of pain, often it was found that before an attack of pain the patient had had a severe nose cold, or some other infection, which had started up the attack. Most of these cases got well after 3 weeks or more of treatment, but the return of symptoms was one of the diagnostic points of the condition. The pain in the upper right quadrant made it difficult to differentiate from gall-bladder trouble. In regard to treatment, every practitioner had his own fads. Personally, he was fond of the bismuth subnitrate. He thought there were better results than with other bismuth preparations. The bismuth should be given before meals as it protected the ulcer during the passage of food. Patients often said that they did better when taking "the white medicine before meals." One hour after meals the patients were given bicarbonate and magnesia. Occasionally calcium was indicated because of diarrhea. Ten grains of oleosaccharate of cloves was used as a carminative to disguise the taste, and to relieve pain. Milk was given 3 hours after a meal and the powder one hour after meals. In regard to the bismuth, it may be mentioned that patients who had had large doses for diagnostic purposes were suddenly relieved of symptoms and felt well for two or three weeks. Roentgenologists have frequently noticed this phenomenon. The salts used were usually the sub-carbonate or barium salts. It was usually better to give the patient a diet list to go by; they were apt to forget verbal instructions as soon as they got out of the office. A dry diet at meal times was better, with glasses of milk between meals. Tea and coffee were almost always badly borne. These patients usually felt better lying down. One could give these patients more rest by means of abdominal supporters of stockinet. Provided no pressure was exerted, this appliance afforded comfort and made for recovery.

Dr. Francis E. Stewart of Philadelphia said that in regard to the use of belladonna, hyoscyamus was more apt to disorder vision than any of the atropine group. In regard to bismuth preparations, the finely divided type of powder penetrated better into the villi of the intestines. Microscopically there was a great difference in the action of the large crystals and of the minute kind. The flavoring of the magnesia salts with aromatics had been patented, so that one might be infringing trade rights in this particular.

Dr. E. McGuire of Richmond, Va., said that he had been very much interested in these papers. He did not hesitate to say that formerly he referred many more cases to the surgeon than he did now. He believed that gastric ulcer should be treated properly to get good results. Absolute rest in bed arrived at this end. He never gave the patient ambulatory treatment if it was by any means possible to put him to bed for two or three weeks. He had made use of the various methods described. He preferred the subnitrate salt of bismuth to the subcarbonate. It was necessary to neutralize the gastric juice. One important thing in cases with retention was that these people should have their stomachs emptied at night. This should be done at 10 P.M. with the stomach tube. At 8 A.M. the patient was fed. The stomach was thus put at rest for the night. Four or five years ago he had a case with retention of 400 c.c. The case was *x*-rayed. The man had lost 35 pounds and begged to have something done for him. The stomach of this patient was emptied every night. He was put on a diet and had alkalies. In five or six weeks he improved very greatly. The treatment was continued and after 5 months the man was perfectly well, had regained his weight, and there was no sign of retention. That case was due to inflammation of the submucosa and when the ulcer was relieved the opening became larger. Therefore these cases were not now referred to the surgeon until efforts had been made toward relieving the obstruction by medical treatment. Dr. Morris had spoken of gastroenterostomy, but three-fourths of these cases had the ulcer situated on the lesser curvature, where no surgeon could possibly reach it. Many of these cases, *x*-rayed after gastroenterostomy, showed that four-fifths of the barium passed out through the contracted opening in the pylorus and not through the gastroenterostomy. He felt that gastroenterostomy was done entirely too often. If surgery was done, it should be excision of the ulcer. A pyloric ulcer could be excised. Their friends, the surgeons, could get much better results if they treated their cases medically for a time. Many cases of ulcer that submitted to operation should never have been touched.

Dr. R. T. Morris of New York said that the discussion had been carried on by experienced men, but what the surgeon would like to ask was what was the easiest way for the patient? If one went to Canada should one go over the falls or across the suspension bridge? There was about that much difference in the treatment. He had had patients come into his office apparently starved. They had traveled to the different resorts, and would have had a good time, only they were starved. He told them to go out and get a good dinner of corned beef and cabbage, with a glass of ale, then, later, they could talk about surgery. Sometimes they did not need much further treatment. In regard to peripheral irritation, some patients had eyestrain, loose kidney, hemorrhoids, or other disturbances. Sympathetic disturbances might give rise to symptoms related to the duodenum. No matter whether the ulcer was cephalad to the duodenum or caudad to the pylorus, one knew, as Rosenow had shown, that the tissues had a selective affinity for toxins. These toxins caused injury to the terminal arterial system, sometimes accompanied by plastic exudate producing endarteritis and increasing susceptibility to bacterial attack upon anemic areas of tissue. They were dealing with a particularly susceptible group of patients who easily succumbed to toxic influences. What happened if one relieved peripheral irritation such as nasal hypertrophy, unerupted molars, etc.? His idea (which might be wrong) was that when the peripheral irritation was removed, the ulcer disappeared, not because it was reflex in origin, but because peripheral irritation had been exciting serious disturbance which resulted in toxic formation in the bowel, causing improper metabolism and tissue changes in the body, and faulty excretion of toxins. Removal of the cause would thus affect the ulcer. That brought in another question, that of more elaborate diagnosis. He had been actively engaged in surgery for 35 years; he did not need to operate on any more ulcer cases. He would rather go fishing, but when the patient came he wished to give that person the best advice he could. Surgery might be suggested for some; for others medical means would suffice. He much preferred to have a laboratory diagnosis made and laboratory facilities applied; by that time the patient had so little money left that the surgeon could not be accused of wanting to charge him a fee. It was very necessary that all of the factors should be worked out in regard to peripheral irritation and focal infection. He had seen many patients recover from ulcer after removal of badly infected tooth roots, with *Streptococcus viridans* infection. In ten patients with this infection there might be no ulcer, but in the eleventh case the patient had become sensitized to the organism. Patients had been known to recover from gastric ulcer after removal of an infected tonsil. It required much more judgment to know just what kind of tonsil should come out, than it required skill to remove it. The psychic factor was a strong one and one that could not be overlooked. Some patients would gain in weight and spirits under any form of treatment for a while. Later they turned up in the hands of some other practitioner. At present the speaker said that he operated only where the radiograph showed distinct obstruction as the result of those "cobwebs in the attic," adhesions. Dr. Aaron had told them that the patients would get well with duodenal lavage even if the kinks were left. Good results had been gained by the Jutte tube. If operation could be avoided, he was glad to avoid it.

On the other hand, patients spent years of invalidism because of neglected operation. One patient of his in New York had made his stomach his occupation for 20 years, and after the removal of four little gallstones, he became a well man. A point to be decided in an association of this sort was to know in just which cases surgery was required. Dr. Satterlee's own case showed that there was a toxic order of events and involvement of the appendix and duodenum simultaneously, as Rosenow had shown to occur. One doctor in New York had recovered from appendicitis without operation, and from that he argued, by his own personal experience that it could be done. He was asked if the personal experience of those who died ought to be considered.

Dr. L. H. Taylor of Washington, D. C., asked Dr. Morris if he had followed up the allergic origin of gastric ulcer.

Dr. Morris said that he had not worked up any further points in the matter. He was still more convinced that allergy was a word one needed to use a great deal in regard to patients who developed ulcer from toxic effects. The patient had become sensitized.

Dr. N. P. Barnes of Washington, D. C., said that in regard to etiological factors, the focal lesion might be very far from the resulting ulcer. No matter whether ulcer occurred or not, any focus of infection, whether in tonsils or teeth, should be removed; one could, however, as Dr. Morris said, make cures by removing the focus of irritation. In regard to diet, one was apt to lose sight of the gastric physiology. Some foods would produce hyperacidity and some would not, but what should one do with the acids of the stomach? Corned beef and cabbage would burn up the acid, but they would train the glands to produce more acid; the carbondioxide, sodium chloride and water would produce more HCl again. Fats and oils lessened the hyperacidity, that was why Dr. Vander Hoof had success with the olive oil, before meals. It acted as a shock absorber. Hyperacidity was a common trouble with pregnant women and very small causes acted to produce it. One saw something bad; one smelt something bad; one got a blow on the knee with acute pain, and the effect was produced. A drug was presented before this society 2 years ago by Dr. Friedenwald, who reported the success he had had with the use of scarlet red. Good results had been obtained with this agent. Magnesium oxide had been used with good result also instead of carbonate of soda.

Dr. W. Wayne Babcock of Philadelphia said that 7 per cent. of men of the first draft were rejected on account of hernia. There were 200,000 cases of hernia sent up for repair. A very large number of men must have been rejected for duodenal ulcer and it became important to know what should be done with these men. A few weeks ago a conference was held of the chiefs of the surgical service in camps and it was stated that in none of the camps had any operation been done for gastric or duodenal ulcer. The consensus of opinion was that operation for ulcer was not to be recommended, because after the operation it would not be possible in the service to arrange the proper diet for a long enough time to make a satisfactory cure. It would not be possible to send the men back with the assurance that they were cured, yet it was possible for many patients to go back to full duty and no severe symptoms, without an operation. This was an important question for the government and for the soldier. The government spent about $200 to fit a man out, and this money was lost if he had to be sent back again. The soldier also had a right to be made as fit as possible. If ulcers could be recognized at the time the man came in, and if he could then be given specialized treatment, he could probably give certain useful service. The former ruling in the army was that if a man needed operation, and the surgeon certified that operation could be done without appreciable risk to the man, and the man refused operation, he could be brought before a court martial. One man was brought before the board for having refused herniorrhaphy and he got off. The new ruling said that if a soldier had any condition which could be relieved by operation, and he refused treatment, he could be tried and punished. Many of these men were afterwards fitted for non. com. service. In regard to ulcers, many no doubt perforated without previous symptoms. Many cases went on to cure without operation. The question of syphilis and ulcer should be considered. The dean of Atlanta medical college said that 60 per cent. of the white patients reporting at their clinics had syphilis, and 85 per cent. of the colored patients, showing that the incidence in all cases was exceedingly large as regarded syphilis. In regard to Dr. Satterlee's experience of ulcer following typhoid immunization, he would like to ask if Dr. Satterlee had had typhoid before. He had seen a case of acute cholecystitis apparently precipitated by typhoid prophylaxis. The man had had old gall bladder trouble. The technique of the treatment of gastric or duodenal ulcer was important. Often surgeons in operating made a slight longitudinal twist by suture. This would produce blocking of the peristaltic impulse with regurgitation and vomiting. If the area of anastomosis were permitted to sink into the lesser peritoneal cavity, or if the opening into the mesocolon were brought down so that part of the jejunum were permitted to get into the lesser peritoneal cavity, the same result would obtain. If the jejunum were not freed the contents would pass back into the stomach so that a large number of secondary symptoms and even deaths that followed these operations were often due to technical errors committed by the surgeon.

Dr. Aaron said that it was the old question as regarded a carbohydrate or a protein diet. He was inclined to think that every man should follow out his own best method of dieting in gastric ulcer. The cause of pain in gastric ulcer had recently been brought out by Carlson, who pointed out that the pains of gastric and duodenal ulcer were contraction pains arising in the stomach or in the pylorus. The contractions were usually not stronger than those of normal digestion peristalsis of the filled or the hunger tonus rhythm of the empty stomach. This pointed clearly to a condition of hyperexcitability of the gastric pain nerves in the ulcer patients experiencing the typical ulcer pains. Therefore ulcer pains were due to tension of excessive contractions or of normal contractions on hyperexcitable pain nerves. As regarded bismuth, the subnitrate was to be preferred to the subcarbonate. Bismuth subnitrate being insoluble in water was chemically inert under ordinary circumstances. A small part of the total quantity introduced in the stomach was decomposed in the acid gastric juice or duodenum, liberating nitric acid, and it was only after this process had taken place that the chemical action of the bismuth began. The chemical action of bismuth within the stomach and duodenum was antisecretory, astringent, and antiseptic. The bismuth subnitrate having been decomposed in the acid gastric juice, it was the simultaneously liberated nitric acid which produced the astringent effect. This astringent process was one of the mildest, but might be made to last a long time, since only a small amount of bismuth was decomposed at a time, and the total quantity remained in the stomach for hours together; the dose, however, should be repeated often enough to supply the loss from disintegration. Thus it was possible, with the aid of bismuth, to maintain a uniform gently astringent process for weeks and months. An objectionable feature of bismuth subcarbonate was that, on entering into combination with hydrochloric acid of the stomach, it released a certain amount of carbon dioxide, which under certain circumstances might give rise to considerable distension of the gastric wall and the ulcer. Besides, the beneficial effect of the liberated nitric acid was lost.

Dr. Satterlee said that he had taken up the subject of duodenal lavage, in kinked intestine with toxemia, and had used the Jutte tube in a series of cases of intestinal toxemia with good temporary result. He then thought he would control these cases by *x*-ray examination as it was not certain the tube went into the duodenum. The tube was *x*-rayed *in situ*. It was found the duodenal tube was often still in the stomach. Epsom salts were used and immediate evacuation of the bowel caused relief. Filling the stomach with fluid was then tried, and at last he came to the conclusion that he was wasting his time with the duodenal tube.

Dr. Aaron asked if the patients had any discomfort from putting fluid into the stomach.

Dr. SATTERLEE said that he thought there was more discomfort in the stomach because the fluid was absorbed in the duodenum. He thought the subject of infection should be more fully emphasized and more attention be given to treatment of tonsils and apices of teeth. The infection must not be forgotten. If ulcers could be treated by argyrol, scarlet red, silver nitrate, etc., the logical way was by local applications. He had not got a large enough series yet. It needed unusual pains, as not one patient in fifty would help in following the case up. One good feature of duodenal lavage was that it caused diuresis, the patients had to pass water at once and sometimes the bowels moved as quickly. Duodenal lavage with saline or salts cleared the bowel of toxic material in a very short time, but in his experience did not cure, any more than epsom salt by mouth cured. The reason was that the wall of the colon and especially the cecum was diseased, infected. He believed these people should be immunized against the autogenous colon bacillus. Many people had been relieved and cured after five years, by immunization by the autogenous organism. All sides of the question had been considered and it was found that the patients came back for the autogenous vaccine. They felt better for it. There was no psychological effect in that. As to operative procedure for the relief of duodenal ulcer, he thought Von Mickulicz's plastic operation was to be preferred, but many ulcers were impossible to remove; they were situated on the posterior wall. In his own case this was so and it was an inoperable ulcer. By making a short no-loop posterior gastroenterostomy with a hole across the pyloric antrum immediate relief was obtained. There was no room for bad results. The toxemia was cleared up and this would no doubt be the operation of the future. Relief of pain helped, but it did not cure. He had tried all preparations of bismuth and he believed that bismuth subnitrate was to be preferred. Magnesium oxide was also given in large doses. The minute a scab was formed there was chance for pus to collect underneath. Alkalies and bismuth should be given simultaneously. Rest would cure any ulcer, but one had to consider the economic status of the patient. If he had to be on the job he must be got into good shape as soon as possible. The question of gastric residue was no argument for or against gastroenterostomy. Many of these casese had been operated on because the surgeon did not know what else to do. The trouble was not there, but lower down. If there was stasis in the appendix or the cecum, there was good ground to work on. The incidence of typhoid in Dr. Freeman's cases was interesting. In his own case, Dr. Satterlee said he had never had typhoid. He had 3 prophylactic injections without reaction, except intestinal symptoms. It was possible that the toxin was irritating to the duodenal mucosa. This was the cause of the ulcer. He had found a vegetable diet the only one suitable to his own case. Most cases could not take meat. The effect of bismuth barium salts upon patients who were *x*-rayed, was due either to sedative or stimulative effects of the *x*-ray. With the continuous *x*-ray series, a large percentage of the patients got better. Improvement in medical treatment should certainly limit the number of operations. He did not see why frequent feedings should be given. It might help the pain but it did not cure the patient. He had tried gastric lavage, but got poor results because the patients were hungry and pain occurred when the stomach was emptied. Gastric ulcer had recurred after excision in a large number of cases, so that results in gastric ulcer had not been so good as in duodenal ulcer. Joseph C. Friedman of Chicago had stated that the pain in duodenal ulcer could be caused by collections of gas due to the spasm of that organ. In some cases that was true and it was in these cases that the free hydrochloric acid was often deficient. Administration of dilute hydrochloric acid helped here, and this was one argument against the theory that excessive hydrochloric acid was the cause of the pain in duodenal ulcer.

Dr. FREEMAN said that in regard to belladonna, he had used the hyoscyamus group. Very few of the patients had complained of eye symptoms. He had also used the drug in his private work and, as a rule, without complaint. In regard to focal infections in the mouth, dispensary cases as a rule had bad teeth. A great majority of them had some infective condition and one could not draw very definite conclusions. Symptoms sometimes failed to yield after the mouth had been attended to. As to hypermotility, any lesion in the gastrointestinal tract might be associated with hypermotility. One reason for making the 18 hour study with the fluoroscope was that in cases where there was appendix or gall bladder conditions, or peritoneal adhesions, one could eliminate these conditions by fluoroscopic study. Where there were upper right quadrant adhesions, the gall bladder was drawn to the right. The duodenum was higher. The hepatic flexure with the colon were drawn towards the gall bladder. There was practically a normal position of the stomach and no increase in peristaltic waves. The stomach musculature was in good condition.

Sera and Allied Materia Medica in War Time.—Dr. A. PARKER HITCHENS of Glen Olden, Pa., presented this subject. In war time the increased call upon physicians, nurses, and hospitals, made it necessary that the civil population be protected as much as possible by prophylaxis against typhoid fever. Prophylactic typhoid vaccine was as certain in its value as that against smallpox; it had no serious effects and it became now, more than ever, the duty of physicians to demand vaccination of all classes against typhoid fever. While the value of prophylaxis against typhoid was assured, the profession were still in a deplorable state of ignorance in regard to the action of bacterial proteins in other diseases. The writer had been studying especially the properties of a vaccine against common "colds" and was certain of its immunizing value. It had been charged that this vaccine was a "shot-gun" prescription, but this fetish could be abandoned, because the vaccines being made in this country against gas gangrene were shot-gun prescriptions in that they were intended to immunize against the *Bacillus welchii*, the tetanus bacillus and the perfringens, at one time. A composite antiserum would be produced. Though not yet sanctioned officially by the army, this was the right line upon which to work. Colds were a mixed infection caused by any organism capable of growing on the mucous membrane of the upper respiratory passages. Some of the best members of the profession at Camp Greenleaf were most enthusiastic about the use of a mixed vaccine to prevent colds, pharyngitis, and even pneumonia. Respiratory infections had been the worst troubles in the camps. Disease below the diaphragm had given no trouble at all. At Camp Greenleaf the streptococcus, the pneumococcus, and the influenza bacillus were the chief offenders. It was necessary before the approach of winter that patients be immunized against the colds that proved so troublesome. The high incidence of lobar and of lobular pneumonia at the camps rendered it imperative before the cold weather to provide a serum of therapeutic value against respiratory infections. Hemolytic streptococcus infection, the source of pneumonia and empyema, must be combated. Cerebrospinal fever was of great interest in the army camps. The value of antimeningococcus vaccine had been tried out. The 89th division at Camp Funston were vaccinated and this division followed abroad to test the immunity conferred. The diagnosis of this disease was not difficult, and if a case of headache were reported, the spinal fluid was examined at once. If the fluid was cloudy, the boy was treated as a case. Headache, vomiting, rash, stiffness of the neck, and Kernig's sign were diagnostic of the disease. Often there were no cerebrospinal symptoms, the disease taking the form of septicemia, toxemia, or joint involvement. Intravenous injection of antiserum was given early, the fluid being allowed to run out slowly, to prevent invagination of the tissues. The head of the bed was raised to get a downward flow. If the patient was extremely toxic, 3 such injections were given in 24 hours. Then the foot of the bed was raised to allow a flow into the ventricles. With early treatment the death rate had come down to 35 per cent. If the organism was very virulent, the death rate was, of course, higher. In civil life boards of health would deal with this matter, not only to save the patient, but to stamp out a focus of infection. Sanitary measures would do a great deal. In gathering men for the

army, however, it must be remembered that the government was gathering together many carriers of common diseases. Active immunization, therefore, in both civil and military life, was indicated at the present time.

Treatment of Empyema in the Army Camps.—Dr. W. W. Babcock of Philadelphia made this presentation. The empyema in the army hospital, he said, was not comparable to the cases in civil life. A 68 per cent. mortality followed pneumonia, and a 95 per cent. mortality followed empyema after measles. The organism was a hemolytic streptococcus. This relation of the organism to high mortality was borne out in all the camps. Many of the Southern troops were debilitated by hook-worm, malaria, etc. Some of them seemed to be the dregs of the population; there were even drug habitués. It looked as if the draft board had put all the undesirables into the army. There were men without fingers or toes; of the first hundred, twenty were morons. Men came with active lesions of syphilis. These men developed virulent forms of measles. The overcrowded state of the camps made hospital treatment difficult. At Camp Wheeler there were 500 beds for 1,300 patients. The venereal cases had to be put into tents. Men were not taken sufficient care of after measles convalescence. On getting out of bed they went to the mess hall, and many felt a chill and became cyanotic. They returned to bed, but the cyanosis and moist rales increased, the breathing would fill up and the case ended fatally. Medical men and surgeons tried all means of treatment. Aspiration and thoracotomy were of no avail. The post mortem showed fluid in the pericardium and the peritoneum, in other words, a polyserositis. Usually the *Streptococcus hemolyticus* was isolated. The blood cultures was positive. The cases were called pneumonia, but the pictures were of great areas of lung congestion. There was purulent peribronchial exudate, but no filling of the alveoli. The patients had a bacteriemia and were very septic. Operation only seemed to shorten their lives by so many hours. The treatment in acute cases was to withdraw the fluid to relieve pressure. Subacute cases without respiratory pressure were more easily relieved. Tuffier's method of introducing into the cavity Dakin's solution, full strength, and then closing the skin, so that the pneumothorax remained and the cavity was sterilized, was tried and in 20 cases 16 recovered. Dakin's solution seemed not to be tolerated in the peritoneum; it dissolved the tissues, but it could be used full strength in the pleural cavity. For a time it looked as if the patients would clear up after it, but many relapsed. For those cases with thick creamy pus, a trocar was used and a graduated tube was put through the intercostal space, and another tube to allow fluid to run out. 100 c.c. fluid was run in and the pus was dissolved so that drainage was free. The deep cavities, however, tended to fill up again. An instrument called the rib-spreader was used to allow of the insertion of the tubes. The conclusion was that under certain conditions it was possible to sterilize an empyema.

The Serum Treatment of Pneumonia.—Dr. F. E. Stewart of Philadelphia presented this topic. (See page 270.)

Dr. Thomas F. Reilly of New York City said that Dr. Stewart's presentation was an excellent summary of the literature of the serum treatment of pneumonia. Last winter in the Fordham Division of Bellevue and Allied Hospitals a fairly extensive use of the serum was made. It was impossible to have a special examination made for the differentiation of the different types, because the technician had gone to war and it would involve the constant use of a messenger both day and night to have the work done at the Main Laboratory, so for a period all cases of pneumonia entering the Hospital were injected with antipneumococcus serum, combined types 1 and 2 of New York City Department of Health. Of 78 patients so injected, 8 died—3 of these died within 12 hours—and 50 per cent. of the cases that died had severe kidney and heart lesions. They were the flotsam and jetsam of New York City and usually the pneumonia mortality among these approximated 30 per cent. During the epidemic because of the inability to get the serum and as a means of checking up non-treated cases, 31 cases were not treated with serum. Of these, 8 died. Usually 60 c.c. were given on the entrance of the patient into the hospital and from 60 to 80 c.c. every 12 hours thereafter. It was the impression, aside from the statistical results, that the serum was of distinct service in the treatment of pneumonia, even though one did not differentiate between the different groups of pneumococci. It was customary to give ½ c.c. under the skin one hour before using the serum intravenously for the first time in order that they might determine the presence of anaphylaxis. There were a few anaphylactic reactions, such as urticaria, arthritis, etc., but none of them were severe. This pneumonia was the ordinary type of pneumonia, such as one sees in practice—lobar in character—and without any bronchopneumonic symptoms. The speaker could not see wherein a *vaccine* could be of any service in the treatment of pneumonia, except as a prophylactic.

Dr. Ernest Zueblin of Cincinnati said he certainly appreciated these papers, but if it became necessary to enforce the giving of typhoid vaccine to all of the civil population, there was a certain amount of danger that should not be overlooked. Quite a considerable number of cases could be quoted in which active pulmonary tuberculosis followed immediately prophylactic typhoid vaccination. Furthermore, it was to be regretted that so little weight and consideration was given by military surgeons to the authentic statements of professional men of good standing attesting the successful prophylactic typhoid vaccination shortly before enlistment. Notwithstanding these statements nurses were revaccinated, and in one instance a severe septicemia was the result, which almost killed the formerly healthy nurse. In regard to pneumonias, it was very desirable that those should be classified according to the characteristic causative microorganism since the classification according to the pathological anatomy was frequently found incomplete.

Dr. N. P. Barnes of Washington, D. C., said that certainly no class of cases gave a better excuse for a death certificate than these multiple pneumonias. People were beginning to excuse the profession if their friends did not get well. The Frenchman said "au revoir," the Irishman said "pneumonia, pneumonia." The profession was coming to the serum treatment. He would like to give personal experience in regard to the dosage. One hundred c.c. of horse serum intravenously was considered the dose, but it was well to test the patient before a large dose by giving a subcutaneous injection and watching the urticarious effect on the skin. The time of operation in these lesions was of the greatest importance. The temperature would be a good guide in such cases; at a certain point of clearing up of the pleural cavity, it came down, and this might be the best time for relieving the pus pressure. Too early operation was contraindicated. He would be glad to hear other opinions as to the best time of operation.

Dr. Jacob Diner of New York said he could fully sympathize with Dr. Bastedo about the material that was being sent to camp. But, as a member of the Medical Advisory Board, he had to hide behind the instructions received from Washington. Specific infections were not allowed to be a bar to active service, whether with a plus Wassermann, or with local lesions. The man with Neisser infection had to go into the army. In fact every man with the usual number of arms, legs, and eyes had to go into the army. They had all been much instructed by the president's paper. He thought sera and vaccines were now being adopted by most surgeons.

Dr. G. R. Satterlee said he would congratulate Drs. Hitchens and Stewart. Dr. Hitchens was launching wonderful work against the *Streptococcus hemolyticus* infections. Dr. Satterlee said he had tried the streptococcus antiserum against infections in other parts of the body, particularly where there was bacteriemia. He had not, however, seen any case really benefited by this vaccine, but this was a field for much future study. He had not had personal experience with the pneumococcus vaccine but he had heard Dr. Cecil's remarks at Albany. His strep-

tococcus percentages were higher at Camp Upton than they were in Rhode Island. Dr. Cecil inclined to the idea that the streptococcus was an end infection and that a certain amount of cross immunization was obtained by streptococcus vaccination, against both streptococcus and pneumococcus pneumonia.

Dr. R. T. Morris of New York said he had had a patient, a young married woman, a fine, strong physical type, about to go on a motoring trip with her husband. She had a rapidly developing tonsillar infection and began to feel weak and ill. The right tonsil showed a streptococcic infection which was treated by argyrol locally. The young woman died in 3 days and a culture made from the tonsil showed *Streptococcus hemolyticus*. Dr. Morris wished to know if any of the members considered if he could have done anything with vaccine in such a case?

Dr. Lewis H. Taylor of Washington, D. C., asked if acroflavine was used or dichloramine-T; how did it compare with Dakin's results?

Dr. E. Zueblin of Cincinnati said he would like to know what observations were made on the tappings of the fluid. This opened a new field for discussion. The action of the Dakin solution on the lung tissue had not yet been observed.

Dr. H. B. Anderson of Toronto, Canada, asked if anyone present had any experience of the effect of vaccine on the severe type of pneumonia, such as described by Dr. Morris. In Toronto there had been this spring the most virulent type of the disease he had ever seen. One patient he had seen died in 24 hours, another in 48 hours; this was a common experience. He had used vaccine in those chronic infections associated with heart trouble, but had not seen any benefit result from their use. He would like to know what result there was from the free opening of the pleural cavity, where there was no walling off by adhesions. Was there any danger of collapse of the lung?

Dr. Babcock said that in regard to spinal puncture in meningitis he was much impressed by results obtained in brain tumor and fracture of the skull with compression of the ventricle. On aspiration there had been jamming down of the foramen magnum, with death. In meningitis there was effusion into the lateral ventricle, which played an important part in the symptoms. He would hesitate to draw fluid from within the brain and ventricle, which might end in jamming the brain down so as to cause death. In one case at Camp Beauregard, the patient was apparently dying of spinal meningitis with symptoms of ventricular distention. The needle withdrew 100 c.c. of turbid fluid and meningitis serum was injected. The patient recovered. In Cushing's cases of effusion into the ventricle, the patient was supposed to be dead. They withdrew the fluid from the lateral ventricle from a subtentorial tumor, and the patient lived for a while. The important thing was to prevent death from ventricular distention. In regard to dichloramine-T—it caused discharge and progressive healing. The destructive action of the solution on the pleura had not been noted. Granulation tissue and adhesions had occurred. There was no effect on the lung whatever. The solution had to be exactly according to the formula of Dakin. Every batch made had to be tested. A degree too much alkalinity caused irritation. If it gave pain or caused trouble there was something wrong. The danger of lung collapse, if the tubes were properly introduced, was very rare. The fluid should be drained off slowly so as not to disturb the heart. In regard to Dr. Barnes' point, as to time of operation, too early operation was not indicated. Some patients had great big walled-off cavities with the lung completely collapsed. These cases had a high mortality.

Dr. Hitchens said that the question of ill effects of typhoid vaccination had been answered by Col. Russell. Instead of being likely to be followed by tuberculosis, it was found that after typhoid vaccination, the incidence of tuberculosis in the army was less than before. Such cases as did happen, were assumed to be coincidence. If the nurses had septicemia following typhoid vaccination, there was some slip in the technique. Someone was at fault. They should not have had it. As to whether this procedure should be recommended in civil life—if there was a good water supply and very few flies, there was practically no typhoid in the community and there was no use in doing unnecessary work. But with contrary conditions, typhoid prophylaxis should be insisted upon. In former years, ten per cent. of the soldiers contracted typhoid. It was practically non-existent in the army to-day. In regard to anaphylaxis, Dr. Stewart would answer that question. Victor C. Vaughan had been studying the question of pneumonia in the various camps and had found a law in regard to the incidence of death rate from pneumonia. Pneumonia in the tropics was a very serious disease and it was more prevalent in the South than in the North. A vivid picture of conditions was presented by two southern camps, only 200 miles apart, showing different mortality and morbidity rates. This difference was based on the communities from which the boys came. The rates were, however, lower than they were in the cities from which they came. It was found that there was a variation in the death rate according to the situation in relation to the Mason and Dixon line and the Missouri River. North of this line the death rate was lower; south of it, higher. If the boys came from Florida and Georgia, the incidence of pneumonia was high. In one camp the negroes came from families who had been north for two or three generations. The death rate was no higher than for white boys, and not so high as for the white troops from the South. Col. Vaughan went back to the statistics of the Civil War and found that the death rate was 18 per thousand per year for the Northern troops, and 63 per thousand per year for the Southern troops. Therefore, it was found that the further south the location, the greater the virulence of the disease. Although the immunization against pneumonia lasted but a few months, it was believed to be well worth while.

Dr. Stewart said he would like to answer Dr. Morris. He thought that 100 c.c. of antiserum could have been employed with advantage in the case mentioned.

(To be continued.)

THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, May 1, 1918.

Dr. Thomas R. Neilson, Acting President, in the Chair.

Report of a Case in Which the Patient Survived the Removal of a Large Tumor of the Brain for Over Thirty Years.—Dr. W. W. Keen presented this report, by himself and Dr. A. G. Ellis, saying that the case was his very first modern brain case and that it showed the then technique, being one of the earliest operations on such tumors, following by only two years Godlee's in 1885. The patient, a man aged twenty-six, had consulted Dr. Keen in May, 1887. When three years of age he had fallen out of a window, striking his head. The skull on the left side was indented and operation disclosed detachment of a small fragment of bone from the inner table without fracture of the outer. Twenty-one years after the fall violent epileptic attacks ensued, followed by intense pain in the head. Paralysis of the right arm, leg, and face had ensued in April, and by August the man had become totally blind, with some intermittence, however, of vision. Some improvement in the paralysis occurred when first seen by Dr. Keen. Operation was performed December 15, 1887, following a course of treatment of potassium iodide. The initial opening was enlarged to 3 x 2½ inches, with the upper margin ¾ inch from the midline. The tumor dipped behind the squamous portion of the temporal bone for ½ inch. The dura was adherent to the brain except at the margin of this large opening. The dura was incised ¼ inch from the margin of the opening in the bone and the tumor readily enucleated. Hemorrhage was free, but not alarming. The tumor was practically a foreign body, starting at the dura as a result of the constant irritation from the little loose fragment of the inner table broken off at the time of the accident. Every inspiration, and especially every impulse from the throbbing heart, produced a slight movement of this

fragment. The tumor weighed 3 ounces 46 grains and proved to be a pure fibroma. Eight days after the operation the floor of the cavity, which was also the roof of the ventricle, evidently gave way, thus opening the roof of the lateral ventricle, and until the fifth week the cerebrospinal fluid continued to escape very freely. At the conclusion of the operation two drainage tubes had been inserted and an abundant gauze dressing applied. The bone could not be replaced as the dura was gone. On the fourteenth day a moderate hernia cerebri, crescentic in shape, had appeared, and from two small pinholes at its middle clear fluid, evidently cerebrospinal, continued to escape until the end of the fifth week. By the seventy-first day the hernia cerebri had subsided until it was nearly on a level with the skull. On the seventy-fifth day this elevation had changed to a deep hollow 5.5 cm. in depth. Twenty-one years after the operation this depression was still present. A striking phenomenon was that whenever the man sat upright, any muscular effort or change of posture, *e.g.* leaning forward, caused this hollow to bulge about an inch beyond the level of the skull. To protect the brain against injury Dr. Keen had bent a piece of tin to fit the surface of his head, covered it with black silk, and sewed this to the inside of a skullcap which the patient always wore. Dr. Keen stated that only three cerebral fibromata appear in Bernhardt and Hale White's table of 580 intracranial tumors. An "entirely favorable prognosis" had been given at the time of operation, and thirty years had fully justified it. The patient died on January 29, 1918, and Dr. M. L. Davis of Lancaster, who had referred the patient to the author, at once advised him, and Dr. Aller G. Ellis procured the brain which the patient had promised to Dr. Keen many years before.

Dr. CHARLES K. MILLS said that he had been present at this operation by Dr. Keen, which was the second one he had seen. The first was by Dr. Weir of New York in a patient of Dr. Seguin. The long duration of life in Dr. Keen's case, with the comparatively good health of the patient, were considered of much interest. Cases of fibromata existing for a long time and not discovered until after death were on record; such a case had been reported in Edinburgh in a well-known physician. Here there had been discovered in a latent region of the brain a flat, hard fibromatous tumor. The appearance and disappearance of the hernia cerebri because of differences in the position of the patient also presented a condition of extreme interest. With the patient in the recumbent position, Dr. Mills observed that the cerebrospinal fluid found its way perhaps through the foramen of Magendie to the spaces around the spinal cord and also possibly into the extra ventricular cerebral spaces. It probably flowed back to its original position when the hernia cerebri was visible. The small amount of paralysis present in the later stage of the case Dr. Mills thought was probably explained by the occurrence of a very gradual compression of the cortex and subcortex allowing a sort of functional adjustment. This had happened in long standing hydrocephalus and offered a more likely explanation than that of compensation by the other hemisphere of the brain.

Tuberculosis in the Army.—Colonel GEORGE E. BUSHNELL, U. S. Army, Retired, said that in examination of men for the Army the welfare of the Army was the first consideration. The examination should be made rapidly with the idea of excluding manifest tuberculosis, of getting the affected men out quickly, and filling their places without delay. The idea of speed was extremely foreign to most examiners. The work was standardized in the Surgeon-General's office and a minimum of fifty examinations per day was one of the directions. The belief held by most of the examiners that it was better to wait until the cases were referred by the regimental surgeons obviously would delay the matter too long, and would, in addition, create the presumption that the disease had been contracted while in the service and was therefore pensionable. The plan created by the Surgeon-General's office tended to prevent too much weight being given to signs of slight organic change. If those believing any evidence of an old healed obsolete tuberculous lesion to be sufficient cause for rejection were afforded time for minute examination many men perfectly fit to serve would be rejected, with injurious results to the Army. As a rule, a man who entered the military service with a not too large quiescent pulmonary lesion improved in the long run in army life. It was directed in the examinations that all cases of active tuberculosis should be rejected, also those with inactive lesions of any considerable size. Quiescent lesions above the clavicle were not regarded as of sufficient size to cause rejection. A further provision was that the diagnosis must be based upon positive signs. Many examiners wished to label some of the cases arrested tuberculosis, retain the men in service, and have them frequently examined. Such a man, however, would be spoiled as a soldier although he might be of the very best physical type. Again, if labeled tuberculosis from the beginning the man would be barred from being pensioned, which would be an injustice. Two schools were represented in the diagnosis of tuberculosis: The old school, which did not make the diagnosis until the signs were clearly marked; the other group perhaps should not be called a school, because it was composed of a number of individuals who do not agree one with another. Recent official word from the French Secretary of War stated that of the 86,000 men said to have tuberculosis in the first year of the war less than 50 per cent. were found upon reexamination to have pulmonary tuberculosis. It was believed by some French authorities that 20 per cent. more truly represents this group. If, however, it were 50 per cent. it would still mean that the transcendental diagnostician was wrong, that tuberculosis could not be safely diagnosed until definite signs were present. This was a vindication of what might be called the old school. While much had been said of the danger of infection of one adult by another, a study of the cases in the French Army showed that the men who had broken down had brought the disease with them. The experience with the repatriated French civilians reported by Dr. Miller was a striking illustration of the fact that even semistarvation and hardships of all kinds did not lead necessarily to the development of tuberculosis on a large scale. In the case of the tuberculous soldier Colonel Bushnell said that the Government had provided seven institutions for the treatment of the disease. The number of men who would remain under treatment would depend upon the matter of their compensation.

Dr. M. HOWARD FUSSELL observed that in the beginning of their work at Fort Niagara he and Dr. Riesman had thought it would be impossible to examine fifty men a day, but had later found this could be easily done.

Dr. THOMAS MCCRAE said that, having had the experience of handling the men from the front in a base hospital, he believed it perfectly absurd to hold the view that a man who had had tuberculosis was probably going to be benefited by going to the front. This was emphasized when considered with the fact of the tremendous strain of being in the trenches, the loss of sleep, the crowding together in small areas, nearly all the men with some bronchitis. He questioned whether any present who had had tuberculosis and who were now in health would consider living such a life. Why then should it be said that probably the soldiers would be benefited by it? Not only in the front line trenches did this apply. It was very significant in his work, particularly with the Canadian soldiers, to find in the labor battalions, where the men were living under healthful conditions, the large number who came in with tuberculosis. Of these probably the vast majority had the disease before. None of us knew, he said, how many cases of tuberculosis in adults were instances of fresh infection and how many were the lighting up of old lesions. The examiner who passed a man with the signs of old tuberculosis was sowing the wind, and the medical officer abroad was the chap who would reap the whirlwind. From seeing the work at the other end of the funnel, he believed that, for the sake of the service and of the man, the matter of examination for tuberculosis could not be too rigid.

Dr. D. J. MCCARTHY said that in presenting to the college a short time ago a review of conditions in the Russian Army he had given figures of the rejections for tuberculosis in the recruits for ten years with the resultant relatively low tuberculosis percentage in the Army. This percentage was lower than that in civil life. Little dependence could be placed upon statistics of repatriated prisoners from Germany

and Austria in estimation of the total number of cases because only the ill were returned.

Dr. CHARLES J. HATFIELD said he should like to bear testimony to the fact that Colonel Bushnell, besides being very enthusiastic, was also very patient, because he received many suggestions from people interested in tuberculosis. Dr. McCrae he thought had given expression to a feeling held by many of the examiners relative to the difficulty of obtaining any standard by which a man with tuberculosis once diagnosed could be legitimately included in the Army. He asked Colonel Bushnell, in this connection, how an examiner, when the signs of tuberculosis had been demonstrated, could certify on paper that the man was sound, that there was no tuberculosis. His understanding was that if the tuberculosis were actually recorded, such record would follow the man, would be known to his superior officer, and that it would have an effect upon his compensation later. He felt that Colonel Bushnell's experience in military service had given him a basis for his opinion of improvement under working conditions, which opinion was to be highly considered. In connection with the National Association, it had been Dr. McCraes privilege to see how splendidly the Surgeon-General's office had considered the question of tuberculosis in the Army and to note its cooperation with outside agencies wishing to have certain conditions fulfilled. He believed that the United States Army to-day, with the various measures enforced by the Surgeon-General, was in a splendid condition.

Colonel BUSHNELL, in closing, said that the difficulty in understanding how a man who had once had signs of tuberculosis could ever be regarded as a safe man depended entirely upon what was meant by tuberculosis, how much tuberculosis there had been, how many bacilli had been present. In his opinion there was hardly a man who, if looked at closely and studied with the *x*-ray, would not show some little signs of abnormality somewhere in the lung. He believed that some examiners could find that 90 per cent. of those present had what some would call evidences of healed tuberculosis. Many men came to him with the diagnosis of active tuberculosis in whom could be found no signs at all. In others giving a diagnosis of healed tuberculosis signs were found varying from a misinterpretation of the normal signs in the right apex to a slight degree of evidence of old trouble. He was increasingly impressed with the fact that many perfectly healthy people showed slight evidences of organic change in the apices of the lungs. One of the most difficult things in medicine was to draw the line of demarcation between that which was normal and that which was abnormal in the apices, and to decide how large a healed lesion a man might have and yet safely be accepted for military service. He observed that now, after three years, it was found that in the French Army probably two whole divisions sent home did not have tuberculosis. In our own Army, of eighty men sent back in one lot, only twenty-five were found by Dr. Webb to have signs of tuberculosis. Those coming over and being sent back cost the Government $5,000. A local and temporary condition, he said, had been called tuberculosis. The same thing was seen throughout the camps. The profession did not get together better on this subject because the pathologist and hospital physician saw only the bad cases while the Army men saw also the good cases.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December, 1917.

(*Continued from page* 222.)

PRACTICE.

1. Give the differential diagnosis between measles and scarlet fever. What complications are likely to accompany or follow scarlet fever, and give their treatment.
2. Give the symptoms, physical signs, and differential diagnosis of acute lobar (croupous) pneumonia.
3. Give the etiology, diagnosis, and treatment of cirrhosis of the liver.
4. Give the clinical symptoms, laboratory findings, and differential diagnosis of Hodgkin's disease.
5. Describe in detail how you would manage a case of typhoid fever so as to prevent its spreading; of tuberculosis; of diphtheria.
6. What is psorias? Give its symptoms and treatment.
7. Give the causes, clinical symptoms, and treatment of arteriosclerosis.
8. Give the symptoms and treatment of chorea.
9. Give the causes, symptoms, and treatment of acute ileocolitis in a child one year of age.
10. What are the chief causes of convulsions in children and infants?

ANSWERS.

PRACTICE.

1. *Scarlet fever:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type, the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent.

Measles: Period of incubation, ten to twelve days. Stage of invasion, four days. Character of eruption, small dark red papules with crescentic borders, beginning on face and rapidly spreading over entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present.

Complications and sequelæ of scarlet fever: Nephritis, adenitis, otitis, arthritis, sore throat, diphtheria, diarrhea, otorrhea, endocarditis, pericarditis.

For the *nephritis*, milk diet, digitalis, diuretics, salines, warm baths, hot packs, and pilocarpine.

For *otitis*, application of heat and puncture of membrane.

For *arthritis*, iron, salicylates, and alkalies.

For *sore throat*, antiseptic sprays, warm applications, ice to suck.

In *diphtheria*, antitoxin, and tonics.

2. ACUTE LOBAR PNEUMONIA. *The first stage* is characterized by sudden onset with chill, a sharp pain in the side, rise of temperature, a short and sharp cough, rusty-colored, viscid sputum, and dyspnea. There may be headache, insomnia, scanty urine with diminution of urea, chlorides, phosphates, and sulphates, insomnia, and herpetic vesicles on the face, and there is always an increase in the number of leucocytes in the blood. Physical examination will reveal diminished expansion, impairment of the normal percussion note, feeble or suppressed respiratory murmur, moist or dry râles, crepitation, and sometimes a pleural friction sound.

In the second stage the dyspnea is more marked; the face is more or less livid in color: the temperature is high (104°-105° F.); and the pulse increases in rate (110-120), its tension and fullness lessening with the progress of the disease, and growing feeble and intermittent. Headache, delirium, and various other nervous symptoms may be present. Expansion is diminished and vocal fremitus is exaggerated upon the affected side. There is dullness with increased resistance over the consolidated lung, and auscultation detects bronchophony or bronchial breathing over this same area.

The third stage is ushered in by a sudden drop of temperature on or about the fifth or ninth day, followed by a natural sleep, free sweating, and relief from suffering. In this stage the crepitant râle (râle redux) is heard in the midst of the bronchial breathing, together with numerous moist râles. Dullness may persist for some time, but usually by the twelfth or fourteenth day the lung has returned to its normal state."—(Gould's and Pyle's *Pocket Cyclopedia.*)

Diagnosis: (1) From *acute phthisis:* The symptoms and physical signs of *lobar pneumonia* and *acute pneumonic phthisis* may be the same for the first eight or

ten days; at this period the fever in *pneumonia* drops by crisis; whereas in *phthisis* the fever continues for some time longer and the patient gets worse; the sputum contains tubercle bacilli and elastic fibers, and instead of retaining the rusty color it becomes purulent and greenish.

In *pneumonia*, the breathing is very rapid, the pulse-respiration rate is disturbed, the fever is usually high, and runs a regular course, crepitant râles are heard at first, then signs of consolidation follow, and crepitant râles again succeed.

In *phthisis*, the breathing is hurried and there is dyspnea, the fever is often high, but does not run a regular course, at first the signs are those of bronchitis, followed by consolidation, a softening, or excavation in different parts of the lungs; sometimes there is nothing to be heard but scattered râles.

(2) From *bronchopneumonia*:

LOBAR PNEUMONIA	BRONCHOPNEUMONIA
Generally a primary disease.	Generally secondary (to bronchitis or an infectious disease).
Age has little influence.	Generally found in very young or very old.
Sudden onset.	Gradual onset.
Fever is high and regular.	Fever is not so high, and is irregular.
Ends by crisis between sixth and tenth day.	Ends by lysis, at no particular date.
Generally only one lung affected.	Generally both lungs affected.
The physical signs are distinct, and there is a large area of consolidation.	Physical signs indistinct, and the evidences of consolidation are indefinite.
Sputum is rusty.	Sputum is rather streaked with blood.

(3) From *acute bronchitis*. *Acute bronchitis* begins with coryza; soreness and tenderness may be behind the sternum; pain may be caused by coughing; expectoration is abundant; dyspnea is in proportion to the extent of the disease; the pulse-respiration ratio is not altered; fever is slight or absent; various râles may be present; the condition is generally bilateral; ends by lysis.

Lobar pneumonia begins with rigors, sometimes also with vomiting; pain on affected side; expectoration is rusty and tenacious; breathing is very rapid; the pulse-respiration ratio is much disturbed; there is considerable fever; crepitant râles are heard in first stage, also in third stage (râle redux) usually only one side is affected; ends by crisis.

Treatment: "Consists in rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60°-70° F.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1/60-1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease."—(*Pocket Cyclopedia.*)

5. *Cirrhosis of the Liver. Etiology*: The prolonged use of alcoholic stimulants, gin, whiskey, beer, or porter is perhaps the most common cause. It may also be due to malaria, syphilis, passive congestion, and irritation of the gall-ducts. The cause may be undiscoverable. It usually occurs in men past thirty-five years of age. The uric acid diathesis may be a causal factor.

DIAGNOSIS OF CIRRHOSIS OF THE LIVER.—"The characteristics of hepatic cirrhosis are the history, area of liver dullness, symptoms of portal obstruction, jaundice, and the course and termination. The distinction between the two varieties is well given by Thayer in the following table:

HYPERTROPHIC CIRRHOSIS.	ATROPHIC CIRRHOSIS.
Jaundice. Early and marked bile often absent from feces.	Late and slight, bile usually present.
Ascites. Late and unimportant.	May be early; often enormous.
Spleen. Enlarged early and markedly.	Late and less.
Alimentary hemorrhage, piles. Not common.	Common.
Liver. Large, smooth, mottled, green.	Small, rough, pale or yellow.
New fibrous tissue. In fine lines and strands between acini and cells, involving all parts equally.	In broad bands, making prominent islands in which the single acinus may appear nearly normal; distributed irregularly.

Atrophy of the liver, or the nutmeg liver, is almost always confounded with cirrhosis; the former occurs most commonly with obstructive diseases of the heart and lungs, and the surface of the organ is not nodulated, nor is there a history of alcoholism.

Cancer and tubercle of the peritoneum have many symptoms akin to cirrhosis. The points of differentiation are great tenderness over abdomen, rapidly developed ascites, rapid decline in strength and flesh, absence of jaundice, absence of long-continued dyspepsia, absence of hepatic changes on percusison, and the presence of tubercle or cancer deposits in other organs."

TREATMENT.—"The diet should be restricted to milk and similar unirritating food. Fatty and saccharine substances should be eliminated. Alcoholic individuals should be advised to cease drinking. The gastrointestinal catarrh should receive symptomatic treatment. Bichloride of mercury, gr. 1/60 to 1/30; gold and sodium chloride, gr. 1/20; sodium phosphate, ʒss to i, and potassium iodide, gr. x, three times daily, are highly recommended. The portal congestion is best relieved by salines. The abdominal dropsy or ascites will require the administration of saline purgatives and diuretics. A half ounce of a concentrated solution of magnesium sulphate taken daily before breakfast is of value, as is also the pill containing 1 gr. each of calomel, digitalis, and squill when given after each meal. Acetate of potassium may also be used. Tapping is necessary when these measures fail. *Surgical treatment*, with a view to establishing an anastomosis between the portal and systemic circulation, has been employed; but it should never be considered in the presence of complicating renal or cardiac disease."—(Hughes' *Practice of Medicine.*)

4. HODGKIN'S DISEASE.—"A hyperplasia of the lymph glands interfering more or less with their functions. The enlargement may be confined to one isolated gland, or a number may be affected in different portions of the body, causing a tumor varying in size from an egg to an orange or even larger. The spleen and liver are involved in two-thirds of the cases. 'The marrow of the long bones may be converted into a rich lymphoid tissue.'—(Osler.) The red blood corpuscles are decreased in number and altered in size and shape; the white blood corpuscles may be slightly increased in number, but there is no approximation to anything like leucocythemia.

Symptoms.—"A slowly developing anemia with isolated or diffused enlargement of the lymphatic glands. As the condition develops, fever of a remittent character occurs, with feeble cardiac action and shortness of breath. The patient grows progressively worse with all the associated symptoms of deficient blood, death occurring by asthenia.

Diagnosis.—"A study of the clinical history will prevent error, as tuberculous or scrofulous glands are accompanied with tuberculous changes elsewhere; and leukemias do not present the same blood picture as Hodgkin's disease."

5. To prevent the spread of typhoid fever: Flies should be kept out of the house as far as possible, by means of screens or otherwise; all discharges from the sick person must be disinfected; all utensils, dishes,

etc., used by the patient must be thoroughly cleansed and boiled every day; soiled linen must be soaked in a disinfectant solution before being washed; after each attendance on a patient, physicians, nurses, and others should wash their hands in a disinfectant; thorough sterilization of all bedding, etc., must be performed after the disease is over. Further, each household should boil all water that is to be used for drinking or for washing dishes, etc.; milk should be boiled also; and no ice should be put *in* water or other drink or food.

"The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation of the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk."—(Parkes' *Practical Hygiene.*)

Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapper in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spitcups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

Treatment of diphtheria: The patient should be in bed and isolated; the family should be quarantined; infected articles should be soaked in some antiseptic solution and then boiled; a milk diet is indicated; the nose and throat should be kept clean by the use of some mild antiseptic solution; calomel in divided doses should be given to keep the bowels open; tincture of the chloride of iron is indicated; and early administration of diphtheria antitoxin in adequate doses (3,000 to 10,000 units) must be given at once; if there is no improvement within twelve hours, the dose must be repeated.

6. PSORIASIS.—A common chronic inflammatory disease of the skin, characterized by variously sized lesions, having red bases, covered with white scales resembling mother-of-pearl. It affects by preference the extensor surface of the body. The lesions are infiltrated, elevated, clearly defined, covered with white, shining, easily detachable scales which, upon removal, reveal a red, punctate, bleeding surface. The eruption is absolutely dry, and itching is usually absent.

The treatment consists of the internal administration of arsenic, cod-liver oil, oil of copaiba, or potassium iodide, and the use of local applications. The scales should be removed by soap and water, alkaline baths, or oily substances. Ointments containing salicylic acid (3 per cent. to 10 per cent.), tar (5ī to 5ī of ointment), ichthyol (5ī to 5ī), chrysarobin (gr. 10-60 to 5ī), ammoniated mercury (gr. 10-40 to 5ī), etc., are very beneficial, and should be used after the scales have been removed." (*Pocket Cyclopedia.*)

7. ARTERIOSCLEROSIS. *Causes.*—"The principal etiologic factors are senility, heredity, male sex, alcoholism, syphilis, lead-poisoning, diabetes, malaria, gout, rheumatism, lithemia, Bright's disease, exposure, and excesses of various kinds. The condition of the arteriocapillary system may be taken as an index of an individual's age. The main factors are 'time, tension, and toxins.'

Symptoms.—These are not always apparent and vary with the arteries involved and their distribution. When the process is general, the peripheral arteries have a hard bony feel, not unlike whip-cord. The increased resistance of the arterial system induces increased cardiac activity and consequent hypertrophy. Attacks of vertigo, pseudo-apoplectic attacks, or spells of unconsciousness in the aged or those having superficial hardened arteries, are generally due to changes in the cerebral vessels. Evidences of myocarditis and angina pectoris point to atheroma of the aorta and coronary arteries. Renal arteriosclerosis manifests itself as chronic interstitial nephritis. Gangrene of the extremities in the old—senile gangrene—point to atheroma or thrombi, the result of the fibrosis.

Treatment.—"The habits, hygiene, mode of life, diet, etc., should be most carefully regulated. When the cause or causes are detected they should be promptly removed. The secretions should be kept free at all times. Constipation should be avoided as it serves to embarrass the functional activity of the liver and kidneys. Alcohol should be interdicted. Moderate exercise is of benefit. Potassium iodide and nitroglycerin should be administered in small doses indefinitely. Overexertion of any kind should be avoided." (Hughes' *Practice of Medicine.*)

8. CHOREA. *Symptoms.*—(1) Irregular and purposeless convulsive movements of the limbs, trunk, face, and tongue, rendered worse on attempting to execute voluntary acts and in fine movements, such as picking up pins, conveying a cup to the lips, writing, or touching a particular point. The movements of the trunk, as the child lies in bed, may cause the body to be first twisted to one side, and then suddenly to the other. The movements cease as a rule during sleep, but may be so violent as to prevent it. The condition may affect one side only (hemichorea). (2) Incoordination, manifested in the movements of writing, in unsteady gait, and in irregular movements of respiration, the diaphragm and intercostal muscles failing to act together. Muscular weakness is a later symptom as a rule. (3) Irregular and rapid action of the heart, sometimes amounting to "delirium cordis." (4) Soft systolic murmurs at the apex of the heart, due to endocarditis, or hemic murmurs at the base. There may be other rheumatic phenomena. (5) Altered mental conditions are sometimes marked, the patient laughing or crying in turns on being spoken to. Increased irritability is common and, in some cases, chiefly in adults, there may be maniacal excitement.

Treatment.—(1) *Rest in bed* is the first and essential point of treatment. (2) Arsenic in increasing doses, cod-liver oil, abundant food, and careful attention to the bowels. Antipyrin or phenacetin in increasing doses is also useful. Salicylates are of value only in rheumatic complications. When the movements are very severe, chloral may be freely given. (3) As soon as convalescence seems established, allow the patient plenty of fresh air and gymnastic exercises."—(Wheeler and Jack's *Handbook of Medicine.*)

9. ACUTE ILEOCOLITIS. *Causes.*—"This form of diarrhea is always caused by microorganisms and the toxins they produce. The organisms gain entrance to the intestines by the food, and multiply with great rapidity. Milk and water are the two commonest vehicles, but fruits and vegetables may carry them into the system. As predisposing causes, unsanitary surroundings and bad domestic hygiene may be mentioned,

and attacks of indigestion caused by improper feeding prepare the way by producing an irritable or unhealthy condition of the intestinal mucosa and lymphatic glands.

Symptoms.—"The attack may begin as a mild diarrhea, and gradually pass into this more severe kind, or it may begin abruptly. The child is restless and peevish, and cries with pain in the abdomen. It looks flushed and feverish, there is more or less vomiting, and a considerable rise of temperature (103° Fahr. or so) is noted. The child wastes rapidly, and there is great loss of weight; the eyes become hollow, and the face is pale; the pulse is rapid, and a typhoid state is often reached. The dejections are thin and watery, brownish or greenish, and very irritating and offensive. The motions are generally accompanied by considerable pain, and much gas; they are usually not more than a dozen in number in twenty-four hours, and are copious. As a rule no blood is passed, except in very small quantity, but there is more or less mucus. The abdomen is considerably swollen, though not markedly tender. There may be considerable tenesmus, and prolapse of the bowel is common. In cases of greater severity the appearance of the child changes rapidly. It becomes very restless, and thirst is urgent. Drinks are frequently called for and taken greedily, only to be vomited immediately. The face is thin and pinched, and the child has an aged look.

The eyes are sunk, and look large and staring, while the skin is dry and has a muddy appearance. The fontanelle is depressed, the temperature rises to 104° or 105° F., the pulse is very rapid and feeble, and convulsions may occur, or a state of coma supervene. When the attack becomes so severe as this, death usually takes place, the fatal event being accompanied by hyperpyrexia, or sometimes by a fall of the temperature to 95° or 93° F."—(*Aids to Diseases of Children.*)

Treatment: "An initial cleansing of the bowel with castor oil or calomel is imperative, followed by starvation for twelve to twenty-four hours. Egg albumin, barley water, or beef broth may be given. Equal parts of beef broth or barley gruel (1 oz. to the pint) are sometimes more acceptable. The tenesmus is relieved by the control of the diet and by the use of codeine, gr. 1/5 to ¼, or Dover's powder, gr. ½ to 2 grains every two or three hours, until the painful symptoms abate. Bismuth subnitrate, gr. 5 to 10, or bismuth subgallate, gr. 2, with powdered ipecac, gr. 1, may be given advantageously every two or three hours for the control of the mucus and blood in the stools. Whey is permitted when the stools show improvement, and after the acute symptoms have subsided sterilized milk is allowed in small amounts well diluted with barley or wheat-flour gruel. Last pasteurized milk is permitted with jellied gruels and broths. The prostration may require hypodermatic medication in the form of atropine, gr. 1/400 with strychnine sulph., gr. 1/250. As a daily routine, one saline irrigation at 100° F. serves a double purpose, as a cleansing solution and for absorption of part of the water. Strychnine sulphate, gr. 1/300, may be given as a tonic three times a day, and astringent enemas for the control of blood and mucus. Silver nitrate (1/1000) or a starch paste in less severe cases may serve the latter purpose. They should not be given more than once daily, and discontinued if the effect is not satisfactory. Too frequent irrigations often cause irritation and aggravations of the symptoms. Removal to the seaside or cool mountain air is a great help in the management, particularly in the convalescent stage."—(Chapin and Pisek's *Diseases of Children.*)

10. *Causes of Convulsions in Children and Infants.*—(1) *Predisposing.*—Hereditary neurotic tendency, rickets, anemia, exhaustion from any cause.

(2) *Exciting.*—Peripheral irritation, as burns, scalds, or wounds, or a pin in the clothing which jags; irritation in the alimentary tract by indigestible articles of food, hardened masses of feces, or worms; dentition, earache, or a foreign body in the ear; retention of urine; sudden chill when the body is heated; fright; congestion or anemia of the brain; the poison of measles, scarlatina, smallpox, uremia, or malaria. Convulsions are common in all affections of the brain and its membranes."—(*Aids to Diseases of Children.*)

(*To be concluded.*)

THE RELATIONSHIP OF ORAL SEPSIS TO SYSTEMIC DISEASE, AND ITS BEARING ON TREATMENT.*

BY H. B. ANDERSON, M.D., L.R.C.P. (London) M.R.C.S. (Eng.).

TORONTO, CANADA.

BASED on clinical observations and investigations carried on during the past few years, I believe it may be stated that "oral infection" is the most important problem before the medical and dental professions at the present time. For years we have recognized in a vague way its serious possibilities. More intensive interest and investigation were stimulated by the writings of William Hunter on its relationship to pernicious anemia. Until the past three or four years, however, attention was centered more on pyorrhea, dental caries, and other more obvious manifestations of oral sepsis, overlooking the fact that the greatest danger was not from these but rather from apical or root infections. The devitalizing of teeth and the sealing up of infection by fillings, or under crowns and bridges, permits the development of serious pathological conditions, with neither symptoms nor obvious signs of the danger menacing the patient's health. In fact, it was frequently those patients who tried to be most careful, who visited the dentist most faithfully, and who had the most extensive and expensive mechanical dentistry carried out, who got into the most serious trouble.

The dental profession, to its credit, has been foremost in warning of the dangers in these cases. This no doubt is partly due to the fact that they were more familiar with the faults and deficiencies of dental technique, and in their routine of work had the best opportunity for observing bad local results.

It is easy to be wise in retrospect, and while evidence as yet does not warrant conclusions, still it is sufficiently suggestive to open a wide field for observation and investigation of the causes for the undoubted increase in certain diseases coincident with the development of mechanical dentistry. The frequency of severe grades of anemia, appendicitis, gastric and duodenal ulcer, gallstone disease, exophthalmic goiter, arterial hypertension, and even diabetes, has been so striking as to call for comment on the part of the laity. In what measure has oral sepsis been responsible for this increase? Sufficient data are not yet forthcoming to answer this question definitely, but they are at least so striking as to call for the fullest investigation.

The removal of teeth is a serious matter, interfering with mastication, and consequently with the kind of food the patient can eat, and, as a result, with his digestion and nutrition. The shock, the opening up of fresh areas for the absorption of pathogenic bacteria and their toxins, involved in the removal of large numbers of infected teeth, especially in the old, the debilitated, and in cases of acute systemic infection, are matters for serious consideration. I have seen two cases of cardiac disease with generalized infection by the *Streptococcus viridans*, evidently due to oral infection, in which death followed and was apparently hastened by extraction. Only a few days ago I saw in consultation a patient practically moribund with acute pneumonia who had been operated on three days previously for a small epithelioma in the floor of the mouth. He was a vigorous railway man, 46 years of age, had never been seriously ill, and the operation was considered trifling. He had marked oral sepsis, and the surgeon extracted some half dozen of the worst teeth in the upper jaw. The patient died on the third day, and cultures from the tooth sockets and the operation wound showed *Streptococcus viridans* and a diphtheroid bacillus, and from the lung a pure culture of *Streptococcus viridans*. The blood culture was sterile.

Some years ago a patient, Hebrew, about 30, was admitted to St. Michael's Hospital, under my care, suffering from an illness which followed extraction of a tooth a few days previously. He had a temperature of 102°, but did not seem seriously ill. In a few days he developed a widespread purpura, hemorrhages from the stomach, bowel, and kidneys, and died in a week.

Suppuration of infected cervical glands occasionally follows extraction. The removal of unerupted teeth, especially, is often a difficult and serious procedure.

I bring these points forward, not as arguments against extraction for the relief of infection, but that it should be undertaken with due care and appreciation of serious possibilities.

Our experience with oral sepsis appears to be, in some ways, another example of the remarkable limitation of human observation and reasoning in regard to what, studied in retrospect, was a very common and obvious cause of disease, as evident as the infectiousness of tuberculosis or the symptom group of Graves' disease, or appendicitis.

In devitalizing teeth, buttressing up infected teeth which should have been extracted, sealing up infec-

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

tion under crowns and bridges, improperly filling root canals, or not filling them at all, incautiously using strong antiseptics, such as arsenic, or causing injury to tissue by direct trauma, dentists were violating scientific principles and thus treading on dangerous ground.

While there are valuable signs presented by ordinary local examination suggestive of root infection, yet in many cases these are insufficient for diagnosis even by skilled and experienced dentists and physicians. *X*-ray examination is of great value, but even this may fail. Expert radiologists frequently differ in their interpretation of *x*-ray films and their clinical significance. The *x*-ray may show rarefaction, but this does not say whether there is an active infection, or whether it is altered tissue where the infection has died out, any more than it can say with certainty whether a lung shadow is that of an active or a healed lesion. Other clinical evidence must be taken into consideration.

We must remember, on the other hand, that at an early stage of infection the bony and other tissue changes may escape detection by the *x*-ray, as they do in early osteomyelitis affecting the long bones; and that the *x*-ray shows the *minimum* rather than the *maximum* amount of trouble.

The angle at which the picture is taken and the overhanging margin of the antrum, present well-known practical difficulties in x-ray diagnosis.

In the mouth of the sick individual containing devitalized teeth, crowns, bridges, pivot teeth, etc., my own experience bears out the *presumption of infection* rather than that of its absence. Every tooth, therefore, should be examined.

A sweetish, offensive breath, swelling and local purplish-red color of the gums, the unusual prominence of certain sockets beyond the general contour of the alveolar margin, the presence of dark teeth, the escape of blood and pus on pressure, hypersecretion of the throat, tonsillitis, whitening of the mucous membrane of the mouth, and miliary enlargement of the lymph follicles beneath it, superficial ulcers, small fistulæ about the bases of the teeth, etc., are points worthy of notice in directing further, and especially *x*-ray, examination. In some cases, however, in which the most careful local examination suggested no infection the *x*-ray has shown the presence of extensive trouble.

All patients with extensive or complete extraction of the teeth have evidently suffered from severe oral sepsis at some time.

The removal of the primary foci of infection, whether in the teeth or elsewhere, does not necessarily mean cure of the condition originally dependent upon such infection. The damage already may have been done, and we may be unable to repair it or to rid the system of infection which has thus gained entrance.

The patient's failure to improve, therefore, after an oral infection has been removed, does not mean that this may not have been the original source of trouble. One should never promise results, but take his stand on the ground that an infection in the mouth, as elsewhere in the body, should be cleared up, whether by conservative or radical means, depending upon the dentist's ability to deal with it. Such dental treatment, of course, should go along with the building up of the patient's health by appropriate general measures. This is a point which is too frequently forgotten.

The importance of trouble short of definite abscess formation, which the radiologist gets around by describing as "rarefaction of bone," thickening of peridental membrane," etc., requires careful investigation. These are the most difficult cases to interpret and to appreciate their clinical significance. We all know that many cases, even with definite abscess formation, may go for a long time without producing evidence of systemic ill health. The latter depends upon the degree of systemic resistance, the character of the infecting bacteria, and the number and extent of infective foci.

Rosenow has shown in his work on gastric ulcer that insignificant foci may be the starting point for general infection. To say that the local condition in rarefaction is due to the action of irritants, such as arsenic, or to traumatic causes, does not disprove the coexistence of infection; for such causes, by reducing the local resistance, predispose to it. We know regarding infection in general that the smallest point may be the port of entry. It is not, therefore, necessary to have many or large areas in order to produce serious systemic trouble in susceptible cases. Therefore, it may not be sufficient to remove only gross lesions—a single point may be sufficient in some cases. In many cases we fail to get the maximum benefit for our patients from neglect of this.

Considered from the viewpoint of general pathology, there is reason to believe that by increasing the patient's resistance many of the slight infections may be overcome. The periodicity of attacks in gastric and duodenal ulcer, gall-bladder, infections, arthritis, etc., with longer or shorter intervals of absence of active symptoms, where the primary focus of infection has not been removed, shows that it may have been at least temporarily overcome by increase of the patient's local and general resistance. "Apparently, the resistance of a large percentage of persons is sufficient to give full protection for years, yet we must ever keep in mind the insidious development of the secondary effects and then ask ourselves if we can be ever reasonably certain that one's health is safeguarded so long as there is definite evidence of infection in the mouth." (Black.)

Rosenow's work on infections has been of the greatest importance, in that it has helped to clear up and coordinate many previously disjointed and fragmentary observations and partial truths. I refer especially to what he says regarding transmutability of organisms and selective tissue affinity. We can now more readily understand why at one time an organism may produce root abscess or tonsillitis, gastric or duodenal ulcer, appendicitis, gall-bladder infection, infective arthritis, etc., and therefore why these conditions are often interrelated and may have a common source of origin.

The recognition of the importance of this interrelationship of disease will have an important bearing not only on the prevention but the treatment of many diseases in the future. In all probability, it will reduce the frequency of operations, because it is obvious that if oral or other focal infections may cause gastric or duodenal ulcer, cholecystitis, appendicitis, or Graves' disease, in many cases our

present surgical methods are attacking the problem at the wrong end, removing the results rather than the cause. If the primary source of trouble remains, the removal of an organ or tissue secondarily infected does not go to the root of the pathological process.

In the preparation of this paper I have studied two hundred and fifty-seven private cases, all seen in office practice, of which I have full histories, and have been able to follow more closely and for a longer period than in hospital practice. They were patients naturally representative of a higher social grade than those found in hospitals. Minor degrees of oral sepsis are not included, owing to the difficulty of appreciating their significance.

I have tabulated these cases, noting the principal disease condition present and also other morbid conditions from which they suffered at the time of consultation or during the course of their illness. From the etiological standpoint this association of diseases is, I believe, of the greatest importance, and one which has not received the attention which it deserves. The frequent association of certain pathological or clinical conditions itself suggests an etiological interrelationship and not accidental occurrence. Autopsy experience impresses one strongly with the fact that pathological conditions found post mortem are usually so related. Clinical observation points the same lesson of a common causative factor, as noted in the complications and sequelæ described in the systematic outline of various diseases. It is a clinical axiom that one should not predicate the existence of two or more unrelated pathological conditions if one is sufficient to explain the symptoms. The more frequently we find two or more pathological conditions associated the stronger is the *prima facie* evidence of their common origin.

Studied from this point of view, cases of oral sepsis present many interesting and instructive features. Various clinical and pathological interrelationships have been recognized for years, as tonsillitis and nephritis; tonsillitis and rheumatism; tonsillitis and appendicitis; tonsillitis endocarditis, erythema multiforme, and chorea; appendicitis cholecystitis, gastric and duodenal ulcer; exophthalmic goiter, and diseases of the other glands of internal secretion, scleroderma, arthritis, etc.; Raynaud's disease, arthritis deformans, scleroderma, purpura, and urticaria; oral infection, tonsillitis, nephritis, and arterial hypertension in some instances.

Oral infections are usually of a low grade of virulence, sealed in, and extend over a long period. To study the evolution of such infections and to appreciate their various clinical manifestations they must be followed for a long time, the same as syphilis and tuberculosis. Private patients, therefore, offer a more favorable opportunity than hospital patients.

Another point I wish especially to emphasize is that if oral infection is shown to have a definite casual relationship to any one disease, as tonsillitis or exophthalmic goiter, it may also be, *per continuum*, the cause of other conditions of which the latter are known to be a starting point.

It is characteristic of oral infections that, as a rule, they do not produce a single systemic lesion, but a group of allied conditions, not all being manifested one at a time. This is shown by the diseases presented in my series of cases, as follows:

Classification of Diseases Associated with 257 Cases of Oral Sepsis.

	Occurring Alone	Associated with Other Diseases	Total
1. Anemia	13	35	48
2. Gastric and duodenal ulcer, appendicitis, gall-stones, etc.	22	25	47
3. Hypertension, albuminuria, kidney disease	27	36	63
4. Mucous colitis	2	3	5
5. Neuritis, lumbago, sciatica, etc.	27	47	74
6. Psychasthenia, nervousness, etc.	28	45	73
7. Raynaud's disease	1	4	5
8. Skin diseases	18	13	31
9. Tonsillitis	4	31	35
10. Goiter	5	22	27
11. Diabetes, miscellaneous	..	....	69
	147	251	477

The associated diseases were usually various groupings of the classes above mentioned.

Mrs. P.
Oral sepsis (the worst case I have ever seen).
Tonsillitis.
Rheumatism, sciatica.
Double antral suppuration.
Eczema.
Urticaria.
Nervous exhaustion.
Exophthalmic goiter.
Anemia, 70 per cent hemoglobin.

Mrs. D.
Oral sepsis.
Tonsillitis.
Migraine.
Raynaud's disesse.
Anemia, 65 per cent hemoglobin.

Miss D.
Oral sepsis.
Tonsillitis.
Nervous exhaustion.
Cystic mastitis.
Rheumatic pains in chest.

Mrs. A.
Oral sepsis.
Tonsillitis.
Quinsy.
Appendicitis.
Neuritis.
Mucous colitis.
Neurasthenia.
Anemia.

Miss T.
Oral sepsis.
Tonsillitis.
Anemia, 70 per cent hemoglobin.
Hypertension, 165.
Erythema multiforme (nodosum et papulatum).
Sciatica.
Albuminuria.

Mrs. Ar.
Oral sepsis.
Chronic appendicitis.
Gastric ulcer (confirmed by operation).
Goiter.

Charles S. D.
Oral sepsis.
Tonsillitis.
Duodenal ulcer.
Sciatica, lumbago.

Miss Au.
Oral sepsis.
Anemia, 65 per cent hemoglobin.
Acne.
Membranous colitis.
Neurasthenia.

John L. B.
Oral sepsis.
Peripheral neuritis.
Arterial hypertension 160-115.
Lymphangitis, edema of legs.
Cardiac decompensation.
Arthritis (feet).
Pleurisy (1916).

Miss L. V. C.
Oral sepsis.
Parotiditis.
Uveitis.
Optic neuritis.
Double facial paralysis.
Secondary glaucoma.
Myocardial weakness.
Anemia.
Intermittent fever.

Miss U.
Oral sepsis (teeth all gone but 2).
Small goiter (Graves' disease).
Tonsillitis.
Laryngitis, bronchitis.
Hypertension, 170-120.
Albuminuria.
Nervous exhaustion.
Arthritis (knees).
Sciatic neuritis.
Brachial neuritis (2 yrs. ago).

Miss J.
Oral sepsis (staphylococcus aureus and streptococcus.
Tonsillitis.
Infective arthritis.
Raynaud's disease.
Erythema multiforme.
Anemia.

Mrs. A.
Oral sepsis.
Psychasthenia.
Colitis.
Sequelae of gastric ulcer.
Appendicitis.

Mrs. B.
Oral sepsis.
Cholecystitis.
Chronic interstitial nephritis.
Arterial hypertension.
Corneal ulcers.

W. R. D.
Oral sepsis.
Tonsillitis.
Appendicitis.
Arthritis (rheumatic, attack o fever).
Brachial neuritis.
Neurasthenia.

Mrs. G.
Oral sepsis.
Anxiety neurosis.
Infective arthritis (knees).
Mucous colitis.

Mrs. G.
Oral sepsis.
Tonsillitis.
Exophthalmic goiter, pulse 120-129.
Infective arthritis (knees).

Mrs. R.
Oral sepsis.
Eczema.
Anemia, 60 per cent hemoglobin.
Glossitis.
Pruritus.
Exophthalmic goiter, pulse 120-150

The above examples from my series of cases are typical pathological interrelationships met with. These various conditions did not, as a rule, appear

at one time, but as phases of a long period of ill health, of which oral sepsis appeared to be directly or indirectly the cause.

Among the diseases before mentioned of which oral sepsis may be the cause there are some to which attention has not been so commonly directed, and which deserve careful observation and further investigation. Among these one may mention exophthalmic goiter, of which I have seen a number of cases where there was very conclusive evidence that oral sepsis was the cause of acute symptoms developing:

Case I.—Ida G. Sept. 7, 1917. Operator, Toronto Carpet Company; robust girl; 2 sisters have goiter, but no toxic symptoms. Patient also has had simple goiter for years. Three or four weeks previously patient complained of pains in upper dorsal region, general malaise, and fever up to 102°-103°. Since illness has been very nervous, emotional, and tremulous. Her mother volunteered the information that her illness followed the filling of a tooth that had been allowed to go too long; her face was swollen and tender after it. At time of my examination patient was exceedingly nervous and excitable; eyes glistening, but not protruding, marked tremor; pulse 120 to 130; gums about upper left molars were red, tender, swollen, and bled readily on pressure; tonsils were inflamed; large firm goiter, not tender; apex beat normal and heart sounds clear; no joint involvement. I suggested tooth as the cause of trouble, and Dr. Fawns had dentist drill it open, when a lot of pus was evacuated. Immediately temperature dropped to 99° and pulse to 88. The opening discharged freely, and she remained well for 5 or 6 days. One day she chewed some gum, which plugged up the opening. Immediately, temperature went up to 100° and pulse to 110. Tooth was then extracted, allowing free drainage, and temperature dropped, but pulse kept up as high as 120. This was afterward explained by the fact that patient was given 5 gr. thyroid extract in place of thyrodectin. As soon as this was discontinued she rapidly improved, thyroid decreased in size, nervous symptom disappeared, and on October 18 she was practically well. This might be considered as an experiment on the production of Graves' disease by oral infection.

Case II.—Mrs. P., age 36, first consulted me on Dec. 1, 1916, complaining of neuralgic headaches, mostly on left side; suffered from bad colds; numbness and heaviness on right side of body; attacks of urticaria; rheumatism; sciatica; was depressed and nervous. At time of examination, patient was pale, Hb 70 per cent., skin dry, tongue very coated, breath offensive; had chronic pharyngitis and tonsilitis; teeth very septic. Dr. McDonagh made *x*-ray examination, and reported left upper second bicuspid, left upper cuspid, lateral and central, all septic, and left first bicuspid should be tested for vitality. There were sinuses opposite the left upper lateral and the posterior molars through which pus could be expressed by pressing on the left side of the roof of the mouth internally, and on the left side of the nose; about the angle of the eye, externally. On removing the tooth the antra on both sides were opened up and discharged pus; *x*-ray examination also showed extensive necrosis of the alveolus. The antra eventually closed up satisfactorily. During early part of treatment, after extended extraction of teeth, etc., patient's health deteriorated, she lost weight, became very weak, scarcely able to walk, but began gradually to regain her health. Wassermann was negative.

March, 1918, wt. 117, Hb 95 per cent., sleep fairly good; still complains of tiring out readily. Considerable involvement of bone still remained, but it was deemed best to temporize, as she was improving. On my advice, she went to Atlantic City. While there she became very nervous, did not sleep, and on her return to Toronto I examined her on May 1, when her weight was 112 pounds, and she complained of numbness in the whole of the right side of the body, jerking and twitching. Her eyes were bright, and slightly prominent; she had distinct tremor in the fingers; pulse 120; marked thyroid enlargement, mostly the middle lobe. May 11. Feeling better, pulse still 120°, very nervous, very marked tremor and thyroid enlargement. Tonsils small; buried; pus readily expressed from crypts. *S. viridans* in cultures. June 18, tonsils removed by Dr. Wishart.

Associated diseases, oral sepsis, tonsillitis, double antral suppuration, rheumatism, sciatica, urticaria, anemia, nervous exhaustion, exophthalmic goiter.

Case III.—Miss A., age 25, nurse in training, not robust, but never suffered any acute illness except recurring attacks of tonsillitis, following last of which she developed rheumatic pains, grating in both knees; ankle joints are still so stiff that she walks with difficulty. Tonsils were removed in Minneapolis some months ago, but no improvement. Thyroid gland is moderately enlarged, uniform in outline, quite firm. Eyes glistening, but not especially prominent. Slight tremor in fingers, general nervousness; pulse 120; *x*-ray examination by Dr. McDonagh showed left upper first molar and right lower first molar to be septic. Oral sepsis, infective arthritis, Graves' disease. On removal of septic teeth, rheumatic condition cleared up, as well as symptoms of Graves' disease.

Some years ago I saw in consultation a patient with slight thyroid enlargement and symptoms of a mild type of Graves' disease, also neuritis. She had extensive crowns and bridge work with marked evidence of infection, but as she had paid a large sum of money for the dental work she refused to have it disturbed, and submitted to thyroidectomy. In the light of recent investigations surely this was not the proper treatment.

Recently I was consulted by a physician, age 42, suffering from severe exophthalmic goiter, marked cardiac dilatation, enlargement of the liver, with jaundice, albuminuria, and casts. He had marked oral sepsis associated with numerous gold crowns. His condition was such as to preclude extensive extraction at the present time, and yet I do not believe he will improve appreciably until the oral trouble is cleared up.

In my series of cases, 257 of oral sepsis, I have had 27 of exophthalmic goiter, in 5 cases alone, in 22 associated with other disease conditions. In one patient there was marked tenderness on pressure over the gland. My own experience fully confirms that of others that oral infection is one of the causes activating the thyroid in exophthalmic goiter, and, like tonsillitis and other focal infections, should be carefully considered in the treatment of this disease.

In diabetes the evidence is not so conclusive, yet the interrelationship of diseases of the ductless glands is well recognized. This has usually been put down to the action of hormones, but could as readily be explained by infection attacking tissues similar in structure. It is well known in the treatment of diabetes that infection will at times cause return of glycosuria without change in diet.

Oral sepsis has long been recognized as an accompaniment of diabetes, but has generally been considered *a result* of the constitutional condition. I believe experience warrants our considering it as a possible cause of the disease. In my series of cases was one showing marked oral sepsis, goiter, acromegaly, arterial hypertension, hemiplegia, and bulbar symptoms.

In certain skin diseases, as the erythema group, purpura, urticaria, eczema, and, I believe, in some cases of lymphangitis, scleroderma, and Raynaud's disease, oral infection should be borne in mind as a possible cause. In my series there were five cases of Raynaud's disease, four of which were associated

with other diseased conditions commonly found accompanying oral sepsis.

Oral infection may be contributory to the development or aggravation of arterial hypertension in some instances. There is no clinical doubt that it may be responsible for nephritis and infections of the urinary tract.

Case IV.—W. I. C., May 22, 1917, railway conductor, age 45. Had always enjoyed good health, and applied to the Imperial Life Insurance in May, 1917, for insurance. Urine ws found to contain large amount of albumin, considerable number red blood cells, and large number of pus cells. Was referred to me for examination on June 5, 1917, by Dr. F. J. Farley. Found his teeth to be in horribly septic condition; general physical examination was negative; skin dry, and he looked anemic. Examination of urine showed spec. grav. 1007, moderate amount of pus, distinct trace of albumin; bacteriological examination and inoculation were both negative. Phthalein output showed right kidney 1½ hrs. 10 per cent., left kidney 1½ hrs. 10 per cent. Practically the only treatment carried out was removal of the teeth. After three weeks he called to see me, and reported himself 50 per cent. better, and by autumn had entirely recovered, the urine being quite normal.

Apart from gall-bladder infections, involvement of the liver itself, with recurrent attacks of chills, fever, hepatic enlargement, and jaundice, occurs at times, as illustrated by the following case:

Case V.—R. S. N., August 11, 1917. Age 62; judge; best weight 176, present 146. Moderate in all habits, working under severe strain, prostate removed by Dr. S. Hay three years ago; also stones in bladder. The latter has been irritable ever since; recurring attacks of cystitis. Past winter has been having recurring attacks of chills, slight jaundice, loss of appetite and weight, weakness, etc. At the time of my examination the patient was distinctly jaundiced; much emaciated; lips cyanosed rather than pale, skin dry and parchmentlike; mouth contained many crowns, bridges, and fillings, associated with an extreme degree of sepsis. The heart sounds were weak. Blood pressure 95-99 systolic, 75 diastolic. Abdomen was very soft, relaxed, and pendulous; liver markedly enlarged, lower margin palpable to near umbilicus. Never any distinct tenderness over gall-bladder area. Urine contained distinct trace of albumin, also pus and bile. Heart was exceedingly weak, impulse practically imperceptible, and sounds scarcely audible with stethescope. Cultures from the blood at this period were negative.

On September 1, 1917, teeth were all removed, which was followed immediately by an extreme degree of collapse; patient was pulseless, cyanosed, and for a few days his condition was exceedingly critical. Within a short time, however, he began gradually to improve. While chills occurred, they were less severe. His weight had been reduced to 127 pounds. During the next few months the patient continued to have recurring attacks of chills, fever at times rising to 103°, remaining up perhaps 48 hours, or less, accompanied by slight jaundice; general weakness.

On January 18 he wrote me: "I weigh 135 pounds, living almost normal life so far as eating is concerned."

February 6, 1918, weighed 141 pounds; systolic blood pressure 108, color good, jaundice cleared, skin softer and more elastic; hepatic dullness at costal margin; heart sounds clear and of very good quality; mouth in good condition. He was attending to his official duties, feeling very well.

May 20, 1918, he weighed 148, looked perfectly well, and was following his professional duties; he still had slight cystitis. His liver was normal in size, and there was no jaundice. This patient evidently has suffered from a diffuse cholangitis and myocardial weakness due to oral sepsis; cured by extraction of teeth and general treatment.

Tonsillitis and cervical adenitis are commoner and more obvious results of oral sepsis, which should be borne in mind. The tonsils frequently are small and buried, so that evidences of infection may be readily overlooked on superficial examination. Tonsillectomy should not be done until the oral infection is cleared up.

It has definitely been established that inflammations of the uveal tract are frequently due to oral infection. Billings and others have reported cases with the clinical picture of disseminate sclerosis; also cases of iritis presumably due to this cause.

In addition to cases where there is a definite regional localization, others of a more general character occur in which there is more or less malnutrition, with dryness of the skin and nervous symptoms of the neurasthenic type, such as insomnia, fatigue, palpitation, flatulence, etc., where oral sepsis appears to be an exciting cause or at least to play a part.

In conclusion, I would caution against too hasty and sweeping generalizations, but urge that each suspected case be carefully and critically investigated, to determine if oral infection is responsible for or contributory to the symptoms. In my opinion, teeth should not be sacrificed on the advice of the physician; a competent and experienced dentist is best qualified to advise as to the applicability of limitations of dental treatment. In many cases the interests of the patient will be best secured by consultation between dentist and physician.

In connection with the preparation of this paper, my thanks are due to Dr. R. W. Mann for bacteriological examinations and Dr. Harold M. Tovell for assistance in the *x*-ray investigations.

SURGERY IN ITS RELATION TO THE PSYCHOSES AND THE PSYCHONEUROSES.*

By ROBERT T. MORRIS, F.A.C.S.,

NEW YORK.

Horticulturists who have developed a fine variety of plant are sometimes discouraged by the appearance of a blight which undoes the work of many years. Freud is a blight, appearing in the midst of our success with the Virchow method of objective teaching. Virchow taught that every disease depends upon objective factors which may be discovered by an observer sufficiently well equipped. He was the great Liberator, the man who took us away from superstition and from metaphysics in relation to disease. Freud, coming upon the scene as a blight, takes us back into metaphysics and superstition. There is no doubt but Freud has opened the way for new observations and classifications, many of them of value. When a new form of blight strikes the potato crop the phytopathologists have an abundance of material with which to work and to construct new theories. The Freudean conception of mental derangements as being due to repressed desires and conflicting emotions is directly opposed to the surgeon's point of view based upon Virchow's objective teaching.

The surgeon assumes that mental derangement is a symptom, not a diagnostic entity—a symptom like a cough, for instance, which may be produced by many fundamental causes. The delu-

*Read at the annual meeting of the American Therapeutic Society at Richmond, Va., June 7 and 8, 1918.

sions and hallucinations of typhoid fever, puerperal septicemia, alcoholism, and melancholia, let us say, are not very different in character when considered purely from the standpoint of hallucinations and delusions. The four different causes for the same kind of "cough" are apparently far apart, and yet perhaps not so far after all. We assume that the hallucinations and delusions of typhoid fever are caused by certain enzymes resulting directly or indirectly from bacterial influence. In puerperal insanity we likewise assume that the mental symptoms depend upon enzymes of bacterial origin, directly or indirectly. In alcoholism we make the same assumption, the microbe in this case which furnishes the primary enzyme being saccharomyces. In the case of melancholia the surgeon again makes the assumption that the hallucinations and delusions are from an enzymic source. Why do we not speak of typhoid fever as an insanity, and of melancholia as an infection? In typhoid fever the symptoms run an acute course marked by liberation of energy in the form of heat in unusual degree, and for that reason we get to look upon typhoid fever as an infection rather than as an insanity. In puerperal insanity we are one step nearer to the case of mental derangement in which heat does not happen to be liberated in unusual degree. A step nearer still when we come to alcoholism. When we have arrived at a consideration of melcholia the comparative slowness of its development and the absence of the feature of liberation of energy in unusual degree of heat has had the effect of turning our thoughts far away from any classification of melancholia and of typhoid fever as being cousins german in the family of microbic diseases. Many of the other insanities belong in this same group from the surgeon's point of view, but in order to concentrate attention upon the main point let us speak for the moment of melancholia alone.

Hippocrates and Galen seem to have given more thought to the enzymic nature of melancholia than do our modern observers. They referred to symptoms as being due to "humors proceeding from the bowel"—the same locality from which the "humors" proceed in typhoid fever. Aretaeus, one of the best observers after Galen, gave a great deal of attention to the question of melancholia as a disease of intestinal origin.

Let us now take up another point, that of the nature of the enzyme producing certain symptoms similar to those produced by typhoid fever, by puerperal sepsis, or by alcoholism. Melancholia may supervene upon sudden mental shock. It may result from a long continued peripheral irritation like that of loose kidney. "Surely this does not mean the same enzyme," some of you are saying. If the sudden shock and the long continued peripheral irritation both have the effect in common of so disturbing the sympathetic and autonomic nervous centers as to result in disturbance of the digestive apparatus, such disturbance may lead to the development of an excess of certain bacteria in the enteron. If we look on the matter in this way we shall gradually be nearing the surgeon's point of view that a focus of infection may enter into an unusual degree of activity as a result of many factors which lessen resistance of the individual toward bacterial invasion. We need not even assume that it is always the same bacterium which gives rise to symptoms like those of melancholia. Various antibodies and various metabolic by-products called out by the presence of bacterial enzymes may be the particular poisons causing the "cough" known as melancholia.

Why should one patient develop symptoms of melancholia when the next ten people exposed to what would appear to be the same disease factors do not have melancholia? Our newer surgery of to-day assumes that one individual is sensitized, allergic, makes anaphylactic response, whatever one may choose to call it, while the other individuals do not happen to make that kind of response. This, it seems to me, is the keynote of the whole subject of the psychoses. Someone will ask about hereditary influence. In certain families there is hereditary tendency toward "rheumatism" of the sort now known to be bacterial in origin. Certain families may be susceptible to the influences which lead toward mental derangement as other families are susceptible to influences leading toward arrested development of some structure. The surgeon of to-day aims at the removal of peripheral irritations and of focal infections on general principles for improving the status of general health of the community. Surgery aimed directly at cure of the psychoses and the psychoneuroses will be a failure because so many factors are involved, but surgery which removes peripheral irritations and focal infections among the insane and among the psychoneurotics will have many spectacular recoveries from the insanities to its credit.

In this brief paper there is no need for my giving detailed description of cases of my own in which there has been recovery from psychoses and neuroses, but these are sufficient in number to lead me to feel that one of the greater new vistas in the whole new field of medicine is about to be opened.

Laboratory facilities which are required at the present time entail so much expense that public benefaction must stand behind the men who are at work in this field.

616 Madison Avenue.

DRUG ADDICTION AND ITS TREATMENT.*

By JACOB DINER, M.D.,

NEW YORK.

OF THE DEPARTMENT OF PHARMACOLOGY, MATERIA MEDICA, AND THERAPEUTICS, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

History records that the aborigines had recourse to drugs for the purpose of making them less amenable to sensations of disturbances or pain to which they were subject by reason of occupation or by reason of the climate in which they sojourned.

The drugs which have been used for that purpose are numerous. We of to-day, however, have to take into consideration only a select few. There is, to begin with, opium and its derivatives, among which morphine and heroine stand out preeminently as the drugs of choice of the addict. Next to these cocaine, hyoscyamus, cannabis, paraldehyde, and to a lesser extent alcohol, have

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

found their place for similar purposes, but it can hardly be said that the last named are narcotics in the true sense of the word, at least not in so far as habit formation is concerned, unless we perhaps except alcohol, which, however, does not come up for discussion. Admitting, to begin with, that drug addiction is a disease, we should as scientific men, consider it from the same aspect from which we consider other diseases. That is, we must divide it into predisposing and exciting causes, into the phenomena or pathology associated with the disease itself, the prevention of that disease, and last, but not least, the cure of the immediate affliction and the after treatment The predisposing causes leading to drug addiction, no doubt, must be looked for, first in the social condition and conditions of labor which obtain among the civilized people. We all know that as civilization progressed the demands upon man became more and more insistent. Greater energy outlay is demanded daily, and to meet these requirements stimulation, either mental or physical, becomes obvious, nay, becomes almost imperative. Some of us obtain that stimulation by change of work, by vacations, by hobbies which we enjoy and which give us a mental or physical rest or both. Others, less careful perhaps in the choice of their relaxation, have recourse to the handy but injurious drug.

Once in a great while the members of the medical profession are the cause of the contraction of the drug habit. It is quite often a relatively easy matter to relieve a suffering patient from pain by the administration of a narcotic. While I fully realize that it is the duty of the physician to allay suffering and cure disease, yet I believe we should lay more emphasis on the latter part of the sentence, that of curing disease rather than to allay suffering. It is for this reason that I wish to emphasize the wrong which the physician commits when he has recourse to the administration of a narcotic for the purpose of easing suffering rather than attempting to analyze the cause of the suffering and removing that cause.

Another and perhaps a most important factor in the promulgation of the use of narcotics has come into vogue recently. As long as the sale of narcotics was not surrounded with so many restrictions and as long as the legitimate use of narcotics was made relatively easy and the obtaining of narcotics for legitimate purposes was within the reach of the suffering public on the one side and within the scope of the prescribing practitioner on the other, there was no special inducement for any man or class of men to increase the use of narcotics. But within recent years, whether necessary or not, a number of laws, intended of course honestly to reduce the abuse of narcotics, have been passed both in the State legislative body and in Congress, and thus the obtaining of drugs has been made relatively, I say relatively, more difficult.

Because of this increasing difficulty those people who think they have to have the narcotic are willing to pay almost any price in order to obtain it. Commercial history has proven that wherever there is a demand there will be the supply and so, in the case of narcotics, the demand being there it was but a short time before the supply was available. Naturally, of course, that supply was there merely because of the profit there was in it, and the more difficult it was made for the general public or even for the physician to use the narcotic or to prescribe it, the more lucrative was it made for those people to handle it; in fact, it became an inducement for them to increase the use of narcotics by illegitimate means in order to increase their profits.

Summarizing, then, the various factors leading to the contraction of the drug habit we have first the inclination or the desire of people to obtain relief either from mental or physical disturbances; secondly, the need of the drug to overcome suffering associated with pathological conditions, and lastly the vicious habit contracted either through environment or by the activity of the nefarious underground channels, whose object it is to increase their clientele and thereby to increase their profit.

The pathology of the drug addict is rather complex. We do know that while at first the use of the drug diminishes sensation and makes them less susceptible to the discomfort incident to whatever it may be, the sequelæ are a disturbed metabolism and an ever-increasing desire for the drug. The fact that there are actually no demonstrable histopathological lesions does not alter the conditions in any way; it remains a disease associated with certain phenomena and certain symptom-complexes. The principal thing for our consideration, however, is the treatment of the disease itself. This must be divided into prophylactic, immediate, and after treatment.

The prophylactic treatment of the drug addict, or rather against the use of the drug, will resolve itself in making the drug inaccessible to the public excepting where it is needed and advised by a legitimate practitioner for legitimate purposes. The present laws do not accomplish it for various reasons.

To begin with, each State has a different narcotic law. While it is true that we have a Federal law, the Harrison antinarcotic law, it is equally true that it is not a prohibitive law, but rather a revenue law or a registration law. Any physician, and legitimately so, may obtain the drug and use it. Any pharmacist or manufacturer may obtain the drug. But it does not in any way prevent the dissemination of the drug throughout the United States, even though its production and its distribution are fairly well regulated, for the reason that it does not prohibit the importation of the drug into the United States from adjoining countries. So, for instance, Canada on the one side, Mexico on the other, Cuba, and even far-distant countries, are enabled to ship the drug into this country.

It is true that the legitimate importation would necessitate the registration of this drug when imported. But because of the great inducement offered to underground dealers through financial returns which they can obtain therefrom, it has opened up a considerable traffic in these narcotics, and I might say that at least half of the drugs that find their way into this country are smuggled in. Therefore the only way in which such impor-

tation or smuggling into this country can be stopped is by international agreement with other countries, requiring them to exercise as careful and thorough a supervision over the manufacture and export of the drug into foreign countries as we do in this country. Thus every bit of narcotic produced anywhere in the civilized world should be placed under government supervision and every grain manufactured or exported would have to be registered and accounted for. This would be a step in the right direction and is, as I said before, a matter of international agreement.

Furthermore, the general practitioner should exercise considerably more care in the prescribing of narcotics. This would do away with some, I will admit a small, part of the abuse of the drug, but one which is however worthy of consideration. And finally, when a physician finds that he has to use the drug, it is perhaps as well that the patient receive it in such a manner that he will not know that a drug of this type is being administered. Therefore, I advocate the discontinuance of the hypodermic syringe whenever possible and the administration of the drug either by the mouth or in the shape of suppositories by the rectum, or through other body surfaces. Now as to the treatment of the drug addict himself this is quite a chapter and well worthy of consideration.

There are relatively few, if any, of the drugs now in use, the withdrawal of which will not cause untold suffering. Theoretically, we could use the physiological antidote, as for instance atropine, to antagonize the effects of the drug. But we must bear in mind that we are not dealing with the effects of the drug physiologically, but with the pathological conditions induced by the abuse of that drug. Therefore, eliminating of course those conditions in which the need of the drug is prompted by other pathological conditions and suffering incident thereto and considering only the conditions emanating from the abuse of the drug itself, we must concentrate on two things: first, to teach the patient that he can get along without the drug; secondly, we must combat the symptoms which arise with or as a result of the withdrawal of the drug. First of all, as in all other conditions, resort must be had to the elimination of the cause leading to the use of the drug. Secondly, the physical condition of the patient is of great importance. Therefore, we should give the patient a reasonable amount of cathartics and at the same time build up his physical resistance by training, by exercise, by proper employment and the right food, so as to enable him to stand the suffering with greater composure and eventually to help himself to overcome the disease.

In this, of course, we must consider that we are dealing with two kinds of patients: those who are anxious to get rid of the affliction and those who only pretend. With the latter I feel that we can do nothing. But given a patient who is honestly anxious to shake off this nefarious addiction, then we must stand back of him and in every way encourage him to do without the drug, by gradual reduction and by building up his resistance. In order to overcome some of the symptoms a purely symptomatic treatment will, of course, have to be resorted to.

Assuming, then, that we are dealing with a case of frank drug addiction, willing to be cured, we must bear in mind that the first thing to do is to put the patient in a position where he would be unable to obtain the drug except through our own channel or by our own administration. We know that with the best intentions in the world the ability to obtain the drug might lead one into the temptation to get more than the physician treating the case deems necessary. So that we must at once dismiss from our consideration the ambulant treatment of the drug addict. That has been proven repeatedly to be a failure and, therefore, if we are honestly endeavoring to cure the patient we must put him either under the supervision of intelligent and trained nurses at home or in an institution where we can thoroughly and absolutely rely upon our orders being carried out. The first thing to do with a case of that kind, after securing proper nursing, would be elimination. Such elimination should be carried out intelligently and should not tend to weaken the patient's condition. Excessive catharsis is not to be countenanced for a moment.

Among the drugs offering themselves for our consideration magnesium sulphate and pilocarpine are the remedies of choice. Magnesium sulphate, as we know, will effect the desired result either promptly or delayed, according to the dilution in which it is given. If we wish to obtain a delayed effect we must give it in concentrated solution, a 25 per cent. solution without the addition of more water. If we wish to obtain immediate result, as we often do in these cases, we must give it in a dilution not to exceed a concentration of 5 per cent. Plenty of water even beyond that may be given. Pilocarpine may be administered in the form of tablets in doses of 1/10 to 1 5 of a grain two or three times a day. The surroundings should be pleasant. The nurse in charge should be selected with a view of being in harmony with the patient, and all outside disturbances should be excluded, even to the point of forbidding the visits of friends and relatives. The drug itself, whatever it may be, whether it be morphine or heroine, should then come up next for consideration. As an initial step a reduction of the dose to 75 per cent. of the previous dose should be resorted to. This can be continued for twenty-four hours, when a further reduction bringing it down to one-half the previous dose should be applied and within a few days the patient ought to be down to a dose of 5 per cent. or even 2 per cent. of the original dose. When we have reached the minimum which he will stand without any marked discomfort we may continue that for a week or ten days and then try to have him get along without the drug altogether. At all times our personal contact with the patient should be one of cheer and one of physical, moral, and mental support. The food should be nutritious but not rich. The diet should be measured with a view of giving him physical support rather than with a view of over-indulging in his desires. At the same time excessive deprivation of food should not be encouraged.

Should mental symptoms make themslves felt

then we will have to follow the usual rules obtaining in therapeutics; that is, to stimulate when depressed and to depress when overstimulated. In our choice of the stimulant it is well not to indulge or introduce a habit which will take the place of the previous one and which might be just as injurious to the patient. Small amounts of strychnine will answer the purpose admirably. Alcohol should not be given under any circumstances. As a depressant, or rather as a sedative, bromides or hyoscyamus may be used, but in no greater doses than is absolutely necessary to bring about the desired result. Thus the elimination, the symptomatic treatment, the food, the reduction of the drug, and the surroundings or rather the cheerful surroundings are the important matters in the treatment of the addict. But at all times the psychic influence on the patient should be borne in mind. We must be an instructor, a mental instructor, a psychical instructor as well as a physician. We must at all times emphasize the fact and bring it home to the patient that he can get along without the drug, and we must also bring it home to him that he is doing most of the work and can do all of the work necessary to break himself of the addiction. A word to his friends and family, who are familiar with his condition, is also essential. No reference should be made by them to his condition unless it be one of cheer and comfort and encouragement. When we have reached a point where the patient can get along without the drug for some time we must outline a régime of physical exercises, occupation, and pleasure together with the proper diet which will keep him in good physical and mental trim. With the wealthier class this is relatively easily accomplished. But with the mass of the poorer people we must provide that the conditions which primarily drove them to the use of the drug are not repeated again so that they may perchance again have recourse to the drug. In other words, we must provide the after-treatment. For this purpose the State or Federal authorities should take care of the after-treatment of the addict just as they are now taking care of the insane. In fact, if the so-called addict is provided for we will have less need for the insane asylums. An organization similar to the Big Brotherhood is the thing that I have in mind—people who will look after the cured addict, who will more or less regulate his amusements, his entertainments and employment. It is the duty of the medical profession to recognize the condition of this evil and to advocate proper measures, both for the prevention of the treatment and the after-care of the drug addict.

Conclusion.—I have endeavored to draw a bold outline of the causes, treatment, and after-treatment of drug addiction. I wish to emphasize that no definite rule or set of rules can be laid down. Each case must be considered as a distinct entity, offering problems which the physician must solve individually and intelligently. No "cure" exists for drug addiction. But the drug addict can be cured if the physician takes the time and trouble and possesess the intelligence and the patience to carry out some of the principles laid down in this discussion.

THE TRAINING OF PHYSICIANS FOR PUBLIC HEALTH SERVICE.

A PLAN SUGGESTED.

By CARL E. McCOMBS, M.D.,
AND
E. H. LEWINSKI-CORWIN, Ph.D.,
NEW YORK.

1. *General Considerations with Regard to Health Administration.*—In a recent report by Franz Schneider, Jr., former sanitarian of the department of surveys and exhibits of the Russell Sage Foundation, on the activities of municipal health departments in the United States, the author summarizes conditions found in the 163 cities studied as follows: "A fifth of the cities made no inspection of school children; over a third did not offer the ordinary laboratory diagnosis for the commoner communicable diseases; over a fourth made no effort to educate in health matters; nearly three-fourths had no housing law; nineteen-twentieths had no concern with the hygiene of industry; over six-sevenths had no program against venereal disease; over a half had no proper organization to combat infant mortality, and less than a quarter had a coherent program against tuberculosis. Surely, these facts argue for a surprising amount of neglected opportunity. . . . The conclusion becomes inevitable that public health work in this country is in its infancy, certainly as far as application of established scientific methods is concerned."

The picture here presented of municipal health service in the United States is a discouraging one, it must be admitted. Is it not pertinent to inquire why such a situation exists in many municipalities otherwise progressive? The first answer which springs to mind is that health appropriations for municipal health work are inadequate. Unfortunately, this is true.

The following table, taken from the Report of the United States Bureau of Census on Statistics of Cities, 1916, shows the per capita and percentage of total expenditures devoted to health conservation, including health department administration, vital statistics, prevention and treatment of communicable diseases, conservation of child health, and food regulation and inspection in the 213 cities of the United States of more than 30,000 population.

Group	Number of Cities	Population	Per Capita Health Conservation	Per Cent of Total Expenditures for Health Conservation
I	9	Over 500,000	$0.55	2.5
II	10	300,000-500,000	0.55	2.5
III	44	100,000-300,000	0.33	2.1
IV	64	50,000-100,000	0.25	1.9
V	86	30,000- 50,000	0.24	1.8
All cities	213	Over 30,000	0.42	2.3

As shown in the detailed analysis of these figures in the report mentioned, which space does not permit us to reproduce, health conservation receives a smaller percentage of the sums spent by cities for governmental purposes than any other major function of government. That a larger expenditure of money for health service is essential to health efficiency no one can doubt, but appropriations for health service must be spent intelligently. It is not invariably true that the community which spends the most per capita for health work gets the most for its money. Other factors, having to do with

the manner in which health appropriations are spent, play a most important part in determining that efficiency. Among the most important of the factors essential to health efficiency is the training of those charged with the expenditure of health appropriations. It will probably be agreed by all who have had an opportunity to see and study municipal health service in the United States that next to adequate appropriations for health work our municipalities need trained and competent health officers, able to appreciate relative values, and with a clear understanding of the practical problems of municipal health service. The part-time physician, untrained in municipal health work, and devoting a small portion of his time to municipal health service, is still found at the head of many of our municipal health departments, and it is in such health departments that inadequate and inefficient service is usually most evident. The first step, then, in improving municipal health service—even before increased appropriations are demanded—should be the selection of full-time trained public health officers who will know how to plan and carry out the work for which increased appropriations may be necessary, and how to develop existing services with economy and efficiency.

Medical training undoubtedly forms the best foundation for public health work, and in the future, as in the past, the medical profession will be chiefly drawn upon to supply public health officers and workers. It is apparent, also, that with the emphasis on the prevention of disease the demand for physicians in public health work will be increased tremendously in the next decade. The burdens which have been placed upon us as a nation by reason of our active participation in the war have had a decidedly salutary effect in stimulating public health interest. As never before in our history, we have been required to take stock of our health resources. The results of the physical examination of the millions of our citizens who have been called into the service of the Government have opened the eyes of all of us to the pressing need of more adequate and efficient health supervision and health conservation. We realize, as never before, just what part is played by tuberculosis and venereal diseases in sapping our national vitality, and we realize, too, the importance of conservation of child life and the reduction of infant mortality and morbidity, to the end that our resources of health may be made as great as possible. The insistent demand for more satisfactory working conditions in industry is shown in the growing volume of provisions for industrial welfare. It is certain that if the age-old differences between labor and capital are ever to be conciliated, there must be also greater concern on the part of private employers as well as the State and municipality for the health of workers.

At a recent meeting of the New York Academy of Medicine resolutions were adopted urging that the need for special instruction in recognition, treatment, and prevention of occupational diseases be brought to the attention of the authorities of the medical schools of New York City; that special clinics for such diseases be organized under the auspices of the medical schools; that the establishment of similar special clinics be urged upon the authorities of the neighboring towns in which large manufacturing plants are located; and that representatives of large hospitals and dispensaries be impressed with the importance of obtaining all possible information regarding occupational diseases. These recommendations were indorsed by the Associated Out-Patient Clinics of the City, and some of the institutions have already taken steps to compile detailed records of the occupations of clinic patients.

Present tendencies indicate, therefore, that municipal health departments will have to consider all of these problems more seriously. Every progressive health department will be required to meet the demands of its citizens for the better protection of child health, the prevention of communicable diseases, particularly tuberculosis and venereal diseases, and the protection of the health of the workers. Since the results hoped for in health conservation are so largely dependent upon the education of the public, municipal health departments will have to develop also more adequate health educational services.

If, as we have assumed, the physicians of the country are to be called upon to meet the tremendously increased demands for public health work, it is certain that our facilities for training in this field must also be increased. Furthermore, the opportunities for training physicians for public health work will have to be developed in such a way as to economize in time and money of physicians desiring to prepare themselves for it. The physician who has been graduated from a medical college after perhaps three or four years of academic work prior to entering the medical school, and who has, in addition, further extended his period of training into the hospital for one or two years, does not look with enthusiasm upon still further extension of his student days into the post-graduate training school for public health. He wants to begin earning and to break the shell of financial dependency in which he has been confined for so long a time. The post-graduate training schools for public health are, of course, to be preferred for those who can afford them—but they do not and cannot meet quickly and economically the need for the training of the large number of young physicians required for public health work.

In order to definitize the problems of training physicians for public health service, there are four questions which must be answered. These are:

1—What is the nature of the training which physicians desiring to enter public health service should receive?

2—What are the existing opportunities for the training of physicians in public health work?

3—How can such training be provided most economically and efficiently for the citizen and the community, and how can it be made so attractive as to draw young physicians from private practice into the field of public service?

4—What are the opportunities of employment for a physician adequately trained in public health work?

Let us consider in detail the first of these questions—that of the nature of the training which physicians should receive to equip them for public

health work. Public health work deals with practical and palpable problems. Efficient public health service requires on the part of the health officer and his subordinate executives first-hand knowledge of the practical problems of the field. His training must therefore be designed with that in view. A sound and thorough grounding in theory is, of course, indispensable to the health officer, but unless that theory is backed up by sound judgment and good common sense in dealing with the work problems of the field—and these attributes can only be tested out through actual experience in the field—it avails little in making one an efficient health officer.

To put the blame for inadequate health appropriations where it really belongs—municipal health officers are certainly responsible to a very considerable degree, in that they commonly fail to produce for the edification of their appropriating bodies sufficient evidence of the need for the activities which real public health service demands. In short, they do not have a program, supported by facts as to field conditions, which is convincing to men unfamiliar with public health work. The health officer who can come before his appropriating body with a clear, concise statement of what needs to be done—backed up by an array of facts as to exact conditions in the field, and who can demonstrate to the appropriating body and the public in general that he knows what he is talking about, usually has little difficulty in securing the financial support necessary. There are scores of municipal health officers in this country who have little real knowledge of the practical problems of inspection for preventable diseases, industrial hygiene, prevention of infant mortality, medical school inspection, and other field work. If efficiency in public health work waits upon more adequate appropriations, practical field experience for the health executive is essential in order that he may plan field work intelligently and be prepared to show the layman clearly what the cost and benefits of his proposals may be.

Assuming, then, that practical field work is an essential for the training of the physician desiring to become a public health executive, what are the practical problems with which he should be familiar? In order that the problems may be illustrated by services with which physicians, particularly physicians of New York City, are familiar, the services offered by the New York City Health Department have been used as a basis since this department has perhaps reached a higher plane of development, in extent of service at least, than any other municipal health department of the country. These services are, briefly, as follows:

I—Control of preventable diseases as exercised through: (A) Diagnostic and research laboratories; (B) Hospitals for contagious diseases and tuberculosis; (C) Clinics for tuberculosis, venereal diseases and industrial diseases; (D) Field inspection and supervision of contagious diseases in the public and parochial schools; (E) Field inspection and supervision of all communicable diseases in the homes of patients and in institutions; (F) Field inspection and supervision of the health of industrial workers.

II—Promotion of child hygiene and prevention of infant mortality as exercised through: (A) Prenatal home visiting and instruction of expectant mothers; (B) Inspection, supervision and education of midwives; (C) Inspection and health supervision of children in institutions; (D) Infant milk station work; (E) Supervision of the health of children of pre-school age; (F) Medical inspection of school children—and the correction of physical and mental defects through home follow-up; (G) Clinics for school children; (H) Physical examination and health supervision of children applying for working papers.

III—Protection of the food supply as exercised through: (A) Inspection and supervision of the production, manufacture, handling, storage, and sale of foods, other than meat and milk; (B) Inspection and supervision of meat in abattoirs, cold-storage plants, wholesale and retail establishments; (C) Inspection and supervision of milk production and distribution in dairies, shipping stations, transportation facilities, receiving stations, pasteurizing and bottling plants and places of local sale; (D) Supervision of the sale of drugs and pharmaceutical preparations, including patent medicines; (E) Laboratory analysis of milk and other foods and beverages.

IV—General municipal sanitation as controlled by: (A) Investigation of citizen complaints and correction of conditions causing them; (B) Inspection and supervision of sanitation in premises, including homes, lodging houses, hospitals and institutions, hotels, etc., *i.e.* housing inspection; (C) Inspection and supervision of other premises where nuisances are likely to exist as barber shops, laundries, public baths, and comfort stations, stables, etc.; (D) Inspection and supervision of sewage and refuse disposal plants and methods; (E) Fly and mosquito prevention work.

V—Vital statistics—compilation and research, including: (A) Methods of collection, tabulation, analysis and interpretation of records; (B) Methods of checking and improving accuracy and completeness of records; (C) Use of graphic methods in interpreting results.

VI—Public health education by: (A) Preparation and publication of annual reports, bulletins, pamphlets, etc.; (B) Lectures, exhibits, newspaper publicity, posters, lantern slides and moving picture films.

As we have said, the services indicated in the preceding outline are those illustrated in the New York City Health Department, but they are services which are offered or should be offered in every large municipal health department and with few exceptions in *every* municipal health department. They represent a wide field of training but a field of training which, in the light of modern knowledge of what public health service demands, should be made available to every physician desiring to enter public health work.

At the present time excellent courses in public health are offered at the University of Michigan, University of Wisconsin, Detroit College of Medicine and Surgery, Tulane University of Louisiana, University of California, New York University, Ohio State University, University of Pennsylvania, University of Colorado. Similar courses are to be opened at Johns Hopkins this fall. All of these schools provide for a certain amount of practical

field work and the courses vary from one to two or more years. The limitation of time, however, makes it necessary, in all of these institutions, to curtail field work somewhat in order that a sufficient amount of classroom and laboratory work can be given. In all courses it is essential that the student be in residence during the period of instruction, and the smallest item of cost to the physician desiring to avail himself of instruction is therefore the tuition fee, which is nominal in most instances.

Admitting all the advantages offered by these various courses in public health, there are certain limitations to the usefulness of these institutions in training physicians for public health work. We have already spoken of the difficulty which certainly exists of inducing physicians who have already gone through a long period of student dependency to continue their studies still further at cost of time and money. Unquestionably, the physician who can afford to spend more time and money in his education for public health work should be encouraged to do so, but there are thousands of young and able physicians who would like to do so but cannot. Furthermore, it is not believed that the post-graduate training schools offer as wide a range of practical experience as is desirable, and practical experience is, as we have said, a most essential part of the training. How, then, can we make available to physicians practical experience as training for public health work and at the same time conserve for them their time and money—our third question.

The "Learn-and-Earn" Plan.—Health service functions are the same in every municipality—the same things need to be done and the ways of doing them have been more or less uniformly established. Almost every large municipality has contagious disease hospitals, field inspection and supervision of cases of preventable disease, medical school inspection, food and milk inspection, laboratory service, etc. If all of these services could be made available as fields of practical training for physicians already in the service, and for those desiring to enter it, the problem of practical training in public health would be solved for a great many physicians who are unable to attend the post-graduate schools. It would be possible, under such a plan, for the physician to learn and at the same time earn, provided he were given an opportunity by rotation of service to obtain experience in all the field services of a health department. We venture to say that if such a plan were adopted there would be little difficulty in recruiting able young men for public health service. Nor would the community suffer in its health protection or be required to spend more money for health service. In fact, the community would benefit considerably in that the service which such physicians would give would be far better than that now given. We have learned in hospital work that the teaching hospital, *i.e.* the hospital which by cooperation with the medical school provides opportunity for the training of physicians in practical bedside work, gains in efficiency in proportion to the extent of its cooperation with the educational institution. There is every reason to believe that municipal health departments would gain also in direct proportion to their development as training schools for public health service. Furthermore, one of the great evils of present medical municipal health service, namely, that of part-time service by physicians would, it is believed, be eventually done away with. The young physician given an opportunity to earn a salary of perhaps $1,000 or $1,200 a year and at the same time become experienced in all branches of public health work would probably be more than willing to give all of his time to health work.

Under the present plan the physician who enters public health service is in most municipalities a part-time employee. He often accepts such employment because "It pays the office rent." He must divide his day between private practice and public health work, and since in the majority of instances he is more interested in building up his private practice than in becoming a public health expert he leaves public health work as soon as his private practice will sustain him satisfactorily. Then, too, as is usual in municipal health departments, the medical inspector finds himself in a comparatively limited field which becomes more and more monotonous as time goes on because the work which he does is routine work, leaving little to his imagination and offering little opportunity for the broadening of his public health vision. In the New York City Health Department, for example, the medical inspector of schools, once appointed by the civil service commission and assigned to that field, remains a medical inspector of schools for as long a time as he remains in the department, unless by some fortuitous reorganization or readjustment of force he may be transferred to another branch of service. But his public health experience is in any case limited not only by the scope of his special work but also by the part-time performance of an increasingly uninteresting routine.

The working out of a plan of rotation of physicians in municipal health service through all branches of service would not be difficult even if part-time medical service were continued, although the most satisfactory plan for the future would be to make full-time service a requirement with the understanding that such full-time service would mean broad practical training in public health. Let us imagine a course of practical training for a physician just entering the municipal health service in New York City. First, he would be attached for a period of perhaps three months to a contagious disease hospital of the Department of Health. Here he would learn by practical experience the diagnosis and treatment of cases of contagious disease, particularly intubation in diphtheria cases, and also something of municipal hospital administration and procedure—a most valuable part of the training that a municipal health officer should have. Next he should have perhaps six months' service as a field medical inspector in the home visiting, diagnosis and supervision of cases of communicable and industrial diseases, and during this period he should also be assigned to the clinics for tuberculosis, industrial diseases, and venereal diseases. If practicable, some experience in the diagnostic and research laboratories would be of value in rounding out the six months' period. For the next six months he should pass through all the various services of the bureau of child hygiene, including prenatal work, midwife inspection, inspection of child-caring institutions, medical inspection of school children, and

the health supervision of children applying for working papers. Three months more might be spent profitably in food and milk inspection work and another three months in general sanitary inspection. Finally, to round out a two or three years' course of training, he should be assigned as opportunity arises to work in connection with the public health education service in preparing exhibits, delivering lectures, etc., and in vital statistics, compilation, and research. In all of these services physicians can be employed to advantage and if full-time service instead of part-time service were required, far greater work accomplishments would be possible than is now possible with part-time service, and fewer physicians would be required.

The advantages of such a plan would be not merely that a large number of physicians would be well trained in public health work, but that the physicians would have an opportunity to find out for themselves the work for which they are best fitted. A poor medical inspector of schools might be an excellent inspector of industrial diseases, and he would probably wish later to specialize in that work; an unsuccessful clinic physician might find that he could make field investigations of contagious diseases more effectively, and he would undoubtedly direct his attention to epidemiological work. This sifting out of men by virtue of their special predilections or adaptability would eventually mean a generally improved health service for the entire department.

Finally—our last question—what opportunities would be available for men so trained—not only within municipal departments of health, but in other services. The opportunities for trained men—men with broad public health training and experience, are especially good in the health department of New York City and other large cities. In New York City, with but few exceptions, positions of large responsibility in the department of health as directors or assistant directors of bureaus, and as supervisors of various branches of medical field work have been filled by promotion from the ranks—and under the prevailing civil service rules in New York City decided preference is given to the promotional method of filling the higher position. The proposal by the New York City Department of Health in 1917 to extend the district plan of health administration beyond the experimental districts, opened the way—if the plan had been adopted—to the promotion of a great many physicians to positions as district health officers. Under this plan the district health officer would have become in fact a municipal health officer with practically all the duties and responsibilities of a health officer of a city of at least 100,000 population. It is significant that when the New York City Health Department contemplated the extension of the plan of district health control, the number of physicians qualified to act as district health officers was so small that special training courses under the supervision of its own specialists had to be established by the department to qualify and select men who could act as district health officers. The very fact that health department physicians, many of whom had been in service a number of years, were not, in the opinion of the Department, qualified by experience and training to act as executives indicates the weakness of the present plan of assignment of physicians to routine service. Had such a plan as this paper suggests been in effect for a few years, competent trained physicians to act as district health officers could have been found, it is believed, without great difficulty.

As regards opportunities for physicians in public health service in other cities we have only to scan the "Help Wanted" column of the public health and medical journals. For example, in a recent issue of the *American Journal of Public Health*, there were calls for:

A chief social worker with experience in venereal disease propaganda. Salary to start $1,400.

A live health officer for a town of 8,000. Salary $1,800.

An executive secretary for a public health association in a large Western city. Salary $2,000.

A county health officer in a south Atlantic State. Salary $2,500 to $3,000.

A statistician (physician) for a central State health department. Salary $2,000.

A hospital superintendent for a tuberculosis hospital in New York State. Salary $1,500-$3,000 and maintenance.

Medical men for administrative positions, preference being given to men with a year of hospital or public health work. Salaries beginning at $3,000 and promotion to $4,000 and $5,000.

A medical man familiar with hospital and public health problems for editorial work in Chicago or New York City.

These are but a few of the many demands for trained medical men in the public health field, but they illustrate very well the wide range of service in which trained workers are needed. Opportunities are now being offered by industrial corporations for men having experience in industrial hygiene to organize and carry on industrial welfare work; private health associations, chambers of commerce, bureaus of municipal research, and other agencies are seeking trained men with public health knowledge; the United States Public Health Service and state and county health organizations need trained men to direct their work, and if in the future a national department of health is developed, still more trained physicians will be needed. Not only in this country is there a constantly growing need for men with practical experience in public health—a demand which after-the-war health problems will greatly increase—but there will be the widest possible field for such trained men during the reconstruction period in other countries after the war. As yet the salaries paid public health officers and health experts in Allied lines of civic work are not what they should be. But the surest way to hasten the tendency already evident to a higher salary rating of public health workers is to qualify the men who enter public health service so that their services will be worth more. The broader the vision of public health service which its workers receive through the more practical training here recommended, the higher the salaries they will command. The time is coming, and indeed is not far distant, when the health officer's wage will be in direct proportion to his competence.

The plan of practical training of physicians for health work which this paper suggests is offered

chiefly to stimulate discussion as to the practicability of such training in large municipal health departments, such as that of New York City. It is admittedly merely a sketchy outline of principles rather than a nice drawing of the machinery needed.

There are, of course, many difficulties apparent in applying such a plan to municipal work, and perhaps a brief statement of some of these difficulties will assist those interested in crystallizing a more perfect plan. First, there will be encountered in most cities some political opposition to the utilization of a municipal health department as a training school. The argument will be raised that it means waste of the taxpayers' money. There will be also opposition on the part of some part-time physicians already in health department service to any scheme of rotation through various fields of work because it will mean more work for them—already adjusted as they are—to a certain part-time routine. Some other physicians will, of course, be unwilling to change from a basis of part-time to full-time work, and the plan will not, therefore, appeal to them, although, as we have said, full-time service, though desirable, is not absolutely essential to the plan. Then, too, the adoption of such a plan would mean for New York City, at least, a changed civil service procedure, and a changed budget procedure. Physicians would have to be assigned to the health department merely as "health physicians" and their assignment determined by the health authorities instead of being assigned as medical inspectors to certain special fields of work which the budget defines from year to year and for which special civil service examinations are held. The civil service difficulty might be obviated by considering physicians under training merely "probationers," their appointments to be confirmed at the termination of the training period. Their experience while in training and their adaptability to special work should under such circumstances be a factor in determining their civil service ratings and appointment.

But none of these difficulties is insurmountable. If the plan is found to be a sound one and worthy of adoption in the Health Department of the City of New York, all of these difficulties might be eliminated through the proper cooperation of everyone concerned. Its successful operation in the Health Department of the City of New York, which is considered a leader in public health work throughout the country, would mean its adoption in other municipalities and eventually a much higher standard of municipal health service than is evident at the present time. The facilities for the practical, efficient training of public health workers are at our very doors and the men for the work will be ready when the facilities are so organized as to train them without unnecessary sacrifice of their time and money. Is it not practicable to bring facilities and men together on a "learn-and-earn" basis?

Potato Exposition in Germany.—A potato show was held in Berlin, February 19. A new species, named for Hindenburg, is said to surpass all competitors. Potato dishes of all kinds were demonstrated and even potato whiskey. Everything possible was done to promote the cultivation of the tuber, yet the crop has failed.

THE PSYCHIC ELEMENT AS AN IMPORTANT FACTOR IN THE DEVELOPMENT AND TREATMENT OF PEPTIC ULCER.*

By JACOB KAUFMANN, M.D.,

NEW YORK.

A RATIONAL and successful treatment of peptic ulcer may be expected only when we are able to clear up and eventually eliminate those causative factors which, in a given case, provoked the ulcer.

Clinical observations have convinced me that in different cases different factors come into consideration, either more or less combined, or with one cause as the principal one.

To-day I wish to single out for discussion the fact that in one group psychic influences—great emotional display, nervous shock, unduly prolonged or intense mental strain, and overexertion play a prominent causative rôle in the development of the ulcer.

As a rule we are dealing here with high-strung, excitable individuals who are prone to indulge in overactivity. Not infrequently they are strongly built, energetic people who lead a very active life in many respects, and in whose histories we find that periods of mental or emotional excess regularly precede the periods of gastric suffering and ulcer symptoms. In the histories of other cases the mental exertion and the emotional strain do not stand out so prominently as unduly great, but they are relatively so for the given individual. It often happens that smaller psychic annoyances, over a certain period of time cause only a milder form of gastric disturbance until the advent of some greater psychic taxation acutely aggravates the condition, provoking pain and other signs of more severe gastric irritation, eventually leading up to the fully developed ulcer picture.

When we take the trouble to inquire into the mode of living of our patients, we can hardly overlook the fact that a causal relationship exists between psychic activity and peptic ulcer formation. Not so obvious, however, is the mechanism of this causal relation and we enter upon unsafe grounds when we try to explain its working. I shall not venture too far into theoretical fields, but shall restrict myself to the brief sketch of some considerations which may, possibly, yield the basis for an explanation.

The intimate connection between the mental state and digestive activity and its disturbances, long known to the laity as well as to medical observers, was experimentally demonstrated by Bidder and Schmidt, Schiff, and later more extensively by Pawlow, Bickel, Cannon, and others. For our question I refer especially to the part of Cannon's work which deals wtih the influence of emotional states on adrenalin secretion and the influence of adrenalin on the activity of the alimentary tract.

Attempts have been made to correlate the effect of adrenalin on the function of stomach and duodenum, with peptic ulcer formation. Some investigators succeeded in producing gastric and duodenal ulcer in animals by repeated injections of adrenalin while others achieved the same re-

*Read before the American Gastro-Enterological Association in Atlantic City, May 6, 1918.

sult by adrenalectomy.* Clinically it may be pointed out that the type of duodenal ulcer which is observed after extensive burning of the skin may be the result of the destruction of a great part of the chromaffin system in the burned area.

However, not only the adrenals get disturbed by psychic irritation, but with their intimate interrelation, other endocrine glands become involved, especially the thyroid. Experimental research also records the finding of ulcerations in the stomach and duodenum after partial thyroidectomy. I quote these experiments to indicate the trend of opinion of investigators who try to show that dysfunction of the endocrine glands may create the basic conditions for the formation of ulcers.

In speaking of the endocrine function we should bear in mind that it is closely interlinked with the function of the vegetative nervous system, the tone of which on the one hand is said to depend upon the secretion of the endocrine glands, while on the other hand, the activity of the endocrine glands is regulated through stimulation by the vegetative nervous system.

It must be admitted that there is still a scarcity of facts which would support the theoretical claims by demonstrating that internal secretory disorders and the correlate derangement of the vagus and sympathetic nervous system may be responsible for such functional disturbances as spasm, increased secretions of gastric juice with diminished amounts of mucus† which we consider essential elements in the pathogenesis of peptic ulcer.

Furthermore, before we can fully utilize this conception in explaining the causative rôle of psychic influences, other problems will have to be solved; for example, the question why the same emotional and mental upsets provoke in one patient peptic ulcer, in another, bilious attacks, in a third, bronchial asthma, in a fourth, arterial hypertension, in a fifth, Graves' disease, and so forth. It seems that the examination of constitutional characteristics and anomalies, which has lately been greatly stimulated by the study of endocrinology, is throwing a good deal of light upon this intricate question. Without taking up the discussion of this topic we may say, in a general way, that the combined disorders of the endocrine function and of the vegetative nervous system, when provoked by psychic irritation in individuals of a certain type or under certain conditions, react particularly on the stomach and duodenum. This reaction, which manifests itself in spasm and secretory disturbances, may produce erosions. I would like to emphasize that it is the frequent repetition of the reaction which gradually changes the growing initial, anatomical lesion of an erosion into an ulcer, and which finally accounts for the chronicity of the ulcer.

While we may leave it to future investigators to define more specifically the manner in which psychic influences act in bringing about the formation of peptic ulcer, about one point there can be no doubt and that is, that once the causal relationship is recognized we have to take it into account in laying out a plan of treatment.

Whatever other medical or surgical treatment may be indicated, according to the condition which the case presents, the final result, especially the prevention of recurrences, depends to a high degree on the possibility of eliminating further periods of display of harmful psychic influences. With this object in view, we must enlighten the patient on his shortcomings, we must advise him to avoid emotional excesses and to redress faulty habits of mental activity. This may involve a thoroughly revised mode of living and eventually necessitate a change of occupation.

One of my patients, a young lawyer, was subject to periodical mild attacks of gastric hyperacidity. While he was trying an important case in court the gastric disturbance became more and more pronounced as the proceedings drew out over a longer period of time, until one particularly hard day repeated attacks of violent gastric pains occurred, followed by a profuse hematemesis, in court. After a strict medical ulcer treatment the patient fully recovered from the severe anemia and since he remained free from subjective symptoms, he forgot the advice given him, and a year later again conducted a difficult long drawn out case in court, when he met with the same experience of quickly increased gastric suffering winding up with a profuse hemorrhage. This time the advice held good for two years when the perfect recovery led him to think that he now could stand up under the strain of a prolonged court trial. The third hemorrhage coming on under the same circumstances finally convinced him, and after abstaining from the exacting and exciting court work and restricting his activity in law to office work he escaped further attacks of severe gastric suffering and bleeding.

It is certainly not always possible for patients to give up an occupation for which they are temperamentally unfit, nor is it an easy task for them to modify their mental and emotional habits. But the difficulty encountered here is not greater than with other diseases, the treatment of which calls for a different mode of living and a change of occupation. With proper direction a good deal can often be accomplished and when a change is feasible, as in the case quoted, a favorable result may be obtained. On the other hand, experience has made it clear to me that it is the utter disregard of primary causative factors, such as harmful psychic influences, which accounts in many cases for the frequent recurrences with which we are so familiar in peptic ulcer. This applies not only to patients who are treated medically, but just as much to those who undergo operations.

I have the records of a number of patients who, in spite of several successive gastric operations, had recurrences because, in the after treatment, no attention whatsoever was paid to the mental and emotional upsets, which, after a more or less extended interval invariably brought on a renewal of the ulcerative process. One of these patients, a highly neurotic trained nurse, had not less than four gastric operations performed for attacks of ulcer symptoms and hemorrhage. Then another attack with profuse bleeding occurred, a surgeon

*For literature and discussion of the topic, see G. A. Friedman, *Arch. of Diagnosis*, Jan., 1917.

†J. Kaufmann: Lack of Gastric Mucus and Its Relation to Gastric Ulcer. *Amer. Jour. of Med. Sciences*, Feb., 1918.

proposed a fifth opertaion which the patient declined. A study of her history showed that she was very ambitious and periodically indulged unreasonably in overwork, gradually getting more and more excited, and that such periods of mental and emotional excess were usually followed by pronounced gastric suffering often associated with hematemesis.

We must realize that operative measures are not essentially causal methods of treatment. Surgery may deal successfully with the sequelæ of ulcers, with stenosis, perforation, and so forth. A gastroenterostomy may prove helpful in combating the ulcerative process by disrupting a vicious circle; but no kind of operative proceeding, not even the complete resection of the ulcer, will prevent recurrences so long as the original causative factors which provoked the formation of the primary ulcer are allowed to come into play again.

As we have seen, psychic elements may form an important and, we may add, a frequent primary cause.

I stated in the beginning that other exciting causes may provoke the development of peptic ulcers. Among these the reflex irritation from diseased abdominal organs is at present over emphasized; while other causes of irritation, for instance, those due to errors in diet, alcohol and tobacco are disregarded to an astonishing degree. Every one of the various causative factors will have to be taken into account if we wish to secure a more lasting effect than is usually afforded by the customary set methods of medical and surgical treatment.

From my own experiences I have reason to believe that the proper consideration of all causative factors during the initial stages may serve as a prophylactic measure in preventing the full development of the ulcer.

HYSTERIA VERSUS NEURASTHENIA.*

By SIEGFRIED BLOCK, A.M., M.D.,

BROOKLYN, NEW YORK.

There are few more bewildering and indefinite series of symptoms that go into a single medical entity than those that form the groups which are designated by the above title. The general practitioner often calls any illness he cannot diagnose, unless there be a large physical deformity, a functional neurosis. In fact, from a rather extended experience it does seem that many practitioners are not decided, often, into which category to place a given case. This thought prompted the subject of this evening, which the writer hopes will be of much value to us all.

As an introduction, let us not forget to distinguish an imaginary illness from a functional disorder. An imaginary illness is an hallucination of sickness. A functional disease is a disease whose organic cause we are unable to elicit, yet something real is wrong. An imaginary illness is not real. It is a true hallucination. Neurasthenia and hysteria are functional diseases. A neurosis is a functional condition of the nervous system. A psychosis is a functional condition of the mind. A neurasthenic patient is more of a nervous patient, while a psychasthenic is a sufferer from a mental condition principally.

It is not difficult to conceive that an hallucination may take any form, hence paralysis, aphasias, etc., are quite common. In hysteria we also get any kind of symptoms, but neurologists use this term only when definite signs, called stigmata, are present. In this way we have an entity presented just as distinct as typhoid fever or pneumonia. But as in typhoid and in pneumonia, doubtful cases do exist.

An easy way to distinguish to one's self the difference between hysteria and neurasthenia is to conceive the idea that a neurasthenic is hypersensitive to external stimulation, while an hysteric is hyposensitive to the same stimulation. This is not true so much in the physical sense as in the psychological conception of stimulations. For example, sticking a needle into the arm of a neurasthenic make him jump, often before the needle touches the arm. The thought makes him shriek. The hysterical person cares so little that he presents areas of anesthesia. The point I desire to present is a rather original conception of these conditions. A highly neurotic individual has lost control of his power of inhibition. The highest power in man is his self-control. The brave soldier has a high type of nerve makeup, unless he happens to belong to the foolhardy, daredevil type, in whom a question of proper mental development is involved. If he is unemotionally aroused by his fellows in an attack, if he does not care what becomes of himself, he is apt to suffer from hysteria. If such a soldier, of the hysterical type, should be subjected to a sudden shock from a shell or other cause which is strong enough to overpower his "I-don't-care" disposition, he may show a condition which, for the want of a better name, is at present termed shell shock. In other words, shell shock is hysteria caused by the stress of battle. Neurasthenic persons are the least likely to get genuine shell shock.* These two states of make-up are diametrically opposed. When a diagnosis of hysteroneurasthenia is made, it is fair to assume that the diagnosis is unknown positively, and, as in the use of typhopneumonia, or some other combination of illnesses, the term is employed to hide ignorance.

If the mental levels are divided into conscious, unconscious, and subconscious, the hysterical states must be placed in the subconscious class. That is to say, these patients are mostly in a state of mind similar to the dream state. Pierre Janet claims that somnambulism and hysteria are synonymous, and many of the amnesias can easily be compared to a somnambulistic state. When such cases begin to regain their memories they wake up as if from a sleep. So may also be explained many cases of dual personality. As dreams have no influence over the conscious mind, and are frequently forgotten, so a dual personality may have no bearing on the normal working mind. To relate an interesting case which I saw with Dr. Eastman, to illustrate this point, may be in order.

*Read at a meeting of the North Brooklyn Medical Society, Tuesday, May 28, 1918.

*Just now almost every nervous or mental disorder developing in battle is being termed shell shock—from paresis up or down the whole line of nervous disorders.

A foreman of painters in Philadelphia was out of work for several days. He bought a morning paper and saw an advertisement for work. Then he took a Market Street car and was not heard from again until eight months later when a letter was received by his wife from the Cook County Hospital in Chicago stating the man was about to be discharged from the Institution as cured. A few days later he returned home as well as ever. He did not know how he came to this hospital. He had a large abdominal scar for which he could not account. After a time he moved to Brooklyn and we succeeded in getting the following history from him. He was surprised when told what we gathered from our many talks. We succeeded in verifying our story.

It seems on his way to work he saw an auction room where he spent his loose change. Being afraid to tell his wife of his extravagance he pawned his watch and with the money he bought a ticket for Chicago where he obtained employment in a varnish factory. After a time he was seized with what he thought was painters' colic. Anyway he went to a private hospital and was operated on for appendicitis. When his funds gave out they told him he would have to leave and with his wound not fully healed he went to the Cook County Hospital. A letter we received from the hospital stated the man came there, with stitches not removed and fresh dressings on an abdominal wound, and applied for admission. They state that he did not know his name, address, or from whence he hailed. After his stay in this hospital for three months he awoke one morning, expressed surprise to find himself in this institution and gave his Philadelphia address as his home, for which he left very soon thereafter.

This patient had all the symptoms and stigmata of hysteria. These stigmata are so well described in textbooks that I will mention only the most prominent ones. Before doing this as each one is mentioned let us consider it in the light of first intimated as the outstanding element of an hysteria; that is to say, not absolutely conscious in the strict sense of the term—as if the mind were covered with a veil or haze. The right thigh and leg were entirely anesthetic. This anesthesia terminated in a straight line on the level of the scrotum; that is, it was a stocking or legging anesthesia, without any connection with nerve distribution. Pins could be introduced, hot test-tubes applied to this area, and the man said he did not feel them. There was no atrophy, no limping, and no difference in knee or ankle reflex between the two sides. Although the man consciously did not state it, subconsciously he did not appreciate the sticking, etc. He did not care much what we did to him.

His palate was anesthetic. He would not gag nor would the pillars of the fauces move when the pharyngeal reflex was examined. We could put almost any kind of instrument into this area without result. This may be explained in the same way as the leg anesthesia.

His visual field was contracted. Whatever he perceived through his eyes he did so as if he looked through a pipe or a tube. He did not see sideways or in the vertical plane as well as most normal persons do. His retina was partly anesthetic to visual stimuli. The contraction was very concentric, even in both eyes, regardless which colors were used for the test.

His memory was quite normal. His only complaint was general weakness, irritability of temper, and a lack of ambition to work. The tests proved that an imaginary sickness was not his lot, but a real genuine hysteria.

Another case seen with a physician some time ago was that of a lady who became lame one night rather suddenly. She passed under the shadow of an electric light. When she stepped into the round, dark spot she thought it was a hole for a moment and has been paralyzed since. She cannot move her right lower extremity. There is quite some atrophy from disuse. When asleep, if the sole of her foot is tickled she draws it up and turns it, showing that the power of motion is intact.

This lady was brought to the hospital in a carriage by her son. She is now dying from infected bedsores. From lying on her buttocks in the bed which she wets continually she has so worn out her gluteal regions that both ischial tuberosities are exposed. She has been told that by pressing on a certain point along the tibial shaft her paralysis will disappear while pressure is made and that then she would be able to move her foot and leg. She responds very well but she claims she cannot find the place herself although we have marked a spot with iodine. We have tried plaster casts, etc., but have had no luck with her. She also has some of the characteristics of hysteria.

The hysterical persons are always hysterical, but some nerve strain is necessary to bring about a symptom which is severe enough to direct medical attention to the patient.

Neurasthenics are of a different type. These persons suffer from a nervous system which is especially susceptible to exhaustion. They constantly live in a state of nerve tension. They are always at top notch, and it is easy to conceive how much less strain it takes to wear them out who are already overworked than it does to wear out an even-tempered normal individual. They are never at rest. Even when they get up in the morning they complain they do not feel rested from the night's sleep. Many of them have insomnia and do not sleep at all. They worry over trifles, so that when a cause for real worry comes they cannot combat it well, and often get what is called a nervous breakdown or nervous prostration. Thus these people become incapable of prolonged physical or mental work. They become envious of others who are able to accomplish things, they become unhappy, and often give up their occupations in disgust, and at times commit suicide. They always complain of their troubles; even little inconveniences hamper their already partially exhausted condition.

On February 26 of this year Dr. Lippman asked me to see a man who had not worked for several months on account of a nervous condition which he could not make out definitely. The man, about fifty years old, an Englishman, complained of every conceivable symptom of a subjective character. He had headache at times, was constipated, had tremors he said, suffered from insomnia, and was always tired. He had an exceptional opportunity for getting government contracts for work but he did not feel that he should undertake such work in his condition. I saw the man three times at my office. At the first visit after a thorough examination I told him I could see no reason for his feeling so ill and he gathered new hope. He returned in a week and I told him he was somewhat improved. The following week the same thing was repeated and he again returned feeling better. At this latter visit I explained to him that I did not think it was necessary to come so often and that his whole condition was more subjective than anything else. He took this to heart and the same evening committed suicide.

This case is a fair example showing how wrong it is to take away the least bit of hope that these patients have.

Another neurasthenic sent by Dr. H. H. Morton was a man who claimed he could have sexual relations with any woman except his wife. He could not get an erection when he attempted the sexual act with his wife. If he dressed another woman like his wife it was quite satisfactory, but if he dressed his wife like another woman with whom this act could be consummated it was a rank failure. No matter what method he used he was unable to satisfy his better-half. This man is now well after going through the enforced rest-treatment described at the close of this paper.

Doctor X., a physician, with a very large practice among the poorer class of patients, was a patient for six weeks. The principal points of interest in this case are that he made on an average of thirty calls daily. He saw forty or fifty people in his office and had calls regularly each night. He not only acted as physician to his

clientele but was the adviser for what they thought were important matters. He became a nervous wreck, irritable, lost his appetite, was always tired out, and felt his inability to work any longer. He knew he needed a rest, but he was so nervous and impatient that whatever he did he could not remain quiet long enough to get properly recuperated. He was in two different sanatoriums looking for treatment but they "got on his nerve" as he expressed it.

This was a typical case of neurasthenia. Milder types are very commonly encountered in medical practitioners, lawyers, school teachers, ministers, business men, etc.

A lady, the wife of a prominent business-man many years older than herself, had three daughters. The husband treated the wife as a child. The daughters had been in college and are bright, active young ladies with ideas of their own. The father died a few years ago leaving the mother who is about forty-five with these girls over twenty. They were all companions when the father was alive—treated as children of an old gentleman. Now the mother wants to be the ruling factor and the clashes which have been occurring regularly have caused the daughters to seek aid for the mother who was suffering from a fatigue typical of neurasthenia. She was in Florida to recuperate physically, but mentally she was at home and her trip was next to useless. It was necessary in this case also to resort to the enforced rest treatment before a desirable result could be realized. It may be stated that although the daughters moved from the home previous to the enforced rest treatment, mentally they were living in close quarters.

Summing up the cardinal points of difference in these two conditions, they may be briefly tabulated about as follows:

HYSTERIA.	NEURASTHENIA.
Areas of anesthesia.	No areas of anesthesia. Hyperesthesia more common.
Contracted visual field.	No contracted visual field.
Anesthetic palate.	No anesthetic palate.
Most symptoms are *objective.*	Most of the symptoms *subjective.*
Subconscious state of mind predominates.	Conscious mind predominates.
Dreams, somnambulistic states, fugues, dual personalities, etc., common.	Insomnia from disturbed peace, no dual personalities, etc.
Mental apathy to surroundings for objective reasons.	Mental apathy because patient is taken up so much with his own suffering.
Fake attempts at suicide.	May commit suicide when no one is watching.
No especial tendency toward fatigue.	Fatigue an important symptom.
Convulsions common.	Convulsions rare, practically none.
Excessive suggestibility.	Almost incapable of receiving suggestions.
Heredity very common.	Heredity of no importance.
Onset of many of the symptoms abrupt.	Gradual onset.
Cures often abrupt.	Cures very gradual.
May imitate almost any sickness.	No imitation of another disease entity.
More common in females.	More common in males.
Essentially a psychoneurosis.	Essentially a nerve exhaustion.

Treatment.—The treatment of hysteria depends entirely on the individual case at hand. No definite rules can be laid down. If a cause is suspected it should be removed, if possible; especially if there is a familial tendency toward this condition the environs must be altered. These people are very open to suggestion, and any form of treatment appealing to the fantasy of life is valuable. It is for this reason that electric baths, Christian Science, New Thought, chiropractic, osteopathy, magnetic healing, and the thousand and one other kinds of suggestive therapeutics have cures to their credit. The general hygienic procedures, as cleanliness of all the emunctories, simple, healthful diet, moderate exercise, and a correction of all physical defects, must be rigidly insisted upon in each case.

Neurasthenia is treated in a very different way. As in other forms of disease, it is necessary to seek a cause, and remove it, if possible. *Rest* is the essential point to be thought of in every case—rest in diet, rest from irritating environment, rest from physical and mental labor, rest from ordinary forms of medicines which did not bring about the results which were desired. In many cases the patient is too worn out to submit to a quiet life. He cannot go away for several months or a year. He has become so irritable that he cannot be without some form of excitement for any extended period of time. He is impatient. For these and allied conditions the author has devised a new line of treatment which has been in use now about five years in a large number of cases. The results have been very gratifying, and many patients have returned to their former occupations cured.

In a paper of this kind it would take too long to outline the whole treatment, which was first read in detail at the Brooklyn Neurological Society on November 1, 1916, and published in the *New York Medical Journal* the following February. The principle of the treatment is to *enforce* the rest upon the patient. Gradually, in a hospital, or with a trained nurse, mail, newspapers, friends, telephone inquiries, food, etc., are all stopped. Even the room is made dark. By the fourth or fifth day in a hospital these restrictions can usually be enforced. Now the patient is subjected to a course of narcotic medication which keeps him asleep, or at least drowsy. This continues according to the case, and the much sought after rest is obtained. In most cases, two weeks in a hospital are worth more than months at a resort where healthful waters are drunk or a vegetarian diet given as a panacea for all bodily ailments. Before the patient leaves the hospital eliminatives and restorative treatments are ordered. One point to be remembered is that the narcotic drugs must be so altered that the chance of habit formation is eliminated.

In conclusion we must make a proper diagnosis, and not treat an organic condition as a functional disease. As time progresses, many of the so-called functional disorders are being more definitely classified, and what we cannot properly diagnose should not be classed as functional. The author is desirous, also, of emphasizing the fact that the great idea of a sexual background of so many nervous conditions is rapidly waning. Dream interpretation, of course, is an interesting study, and it may have a slight connection with some of these conditions; but in the present state of advancement of medical science it is too abstract to be of much real scientific value.

548 Greene Avenue.

THE BROADENING FIELD OF MENTAL MEDICINE.*

By WM. BURGESS CORNELL, M.D.,

NEW YORK.

MEDICAL SUPERINTENDENT, RANDALL'S ISLAND.

I have undertaken this paper to discuss the present survey and help[illegible] psychiatry and to attempt to indicate what greater opportunities the near future seems to hold in store.

First, however, let us contrast the conditions generally found a few years ago, but now rapidly disappearing from view. Less than two decades have passed since the practice of psychiatry was almost exclusively limited to the hospital for the insane, or asylum as it was almost universally termed. Psychiatry was separate and a thing apart from general medicine. There were several factors which produced this divorcement. First, the isolation of the hospital, usually built seven miles from nowhere and consequently difficult of access, and effectually removed from social and medical centers and general hospitals.

Second, was the general attitude held toward psychiatry and mental diseases by both medical profession and public, which combined apathy or antipathy, ignorance, and superstition. In the medical schools there was very little psychiatry taught, and often none at all. Small wonder then that few young physicians were attracted toward it as a specialty and that those who were came often poorly prepared, or attracted merely by salary and free maintenance as a stepping stone to other branches of medicine. Some, however, were inspired by a sincere effort to live up to high ideals of medicine with hopes of successful research and new discovery. To the latter group let us pay our respects and pause a moment to see what happened irrespective of motive in the majority of instances. Once on the asylum staff the process of divorcement from general medicine and its stimulating interests began and quickly settled into humdrum routine; in a year or two the young psychiatrist became thoroughly institutionalized with ankylosis of initiative and stasis of medical advancement—a life member of the institutional lotophagi. It is interesting to note the development of a definite institutional type among asylum physicians, the product of the old-time routine and lack of sufficient outside interests, as well as the reaction of the generally hopeless and helpless feeling that nothing could be done for the majority of patients.

But fortunately for both patient and physician there has been a psychiatric renaissance. After many dormant years this country at last awoke to the advantages of the European psychiatric clinic in close touch with the university and general hospital, and we note the establishment of the Psychopathic Hospital at Ann Arbor, Pavilion F at the Albany Hospital, Boston Psychopathic Hospital, and the Phipps Psychiatric Clinic all within a decade. It is difficult to realize what a great advance all this represents, so rapid has been the march of events. With new ideas and new hopes, asylums became hospitals, physical restraint began to disappear, and the application of individual treatment as for many other sick patients was inaugurated. With diversional occupation in great variety and a general employment of a large majority of patients, life in a hospital took on new interest for patient, nurse, and physician and gave far better results in recoveries and improvements. The establishment of clinical and pathological laboratories meant greater accuracy in diagnosis, better study of cases, and a more rational and effective therapy, and medical school, general hospital, and mental hospital were brought closer together.

The psychopathic clinic in proximity and cooperation with the medical school and general hospital has stimulated and facilitated the teaching of psychiatry and is greatly increasing the number of medical students who choose it as a career. The psychopathic clinic, easy of access with voluntary admittance, has also done much to dissipate popular superstition and misconception concerning mental disease. But the psychiatric renaissance has reached out beyond the institution, and here the field broadens.

It is now about ten years ago since the first organized effort to supervise and assist discharged or paroled mental cases was made in New York. The value of after-care was at first slow to be appreciated, but of late it has gained in Massachusetts, New York, and Maryland an impetus that will give it widespread application. The hospital residence of an average case is hardly more than a biographical cross-section of the life history of the patient, and no longer is it good practice or good policy to neglect what has gone on before, or to withdraw our interest and assistance as soon as the patient steps out over the hospital threshold. Organized first as a private charity, the State of New York several years ago took over the after-care work that had been begun in 1906; and it is now a regular part of the hospital routine. In 1915 New York and Massachusetts State Hospitals greatly increased their sphere of usefulness by inaugurating dispensary clinics for mental and nervous cases held sometimes at the institution, but often in some city within the hospital district. This innovation, added to the placing out and after-care service, marks a new epoch in psychiatry that will prove to be also an important factor in prevention and will bring the hospital still closer to the public.

The great modern trend of medicine toward prevention has been shared in prominently by psychiatry with large forces actively working in this direction. In addition to the State Hospitals and its newer ramifications above referred to should be mentioned the social service departments of psychopathic hospitals of which Boston, Johns Hopkins, and Bellevue are excellent examples. Mental Hygiene Societies, notably in Connecticut, Illinois, Maryland, and Massachusetts and the National Committee for Mental Hygiene are doing a great public service in disseminating the knowledge gleaned from the hospital, clinical laboratory, and other research agencies. Of the latter, two in particular should be mentioned, the Eugenics Record Office and the Vineland Labora-

*A contribution to the William Leonard Worcester Memorial Series of Danvers State Hospital Papers, presented November 19, 1915.

tory. Both have performed most valuable services in the study of heredity, particularly in strains exhibiting insanity and feeble-mindedness.

It is particularly noticeable how in recent years the focus of interest of psychology and sociology has been toward the deviate and subnormal, and we hear much of practical economic and medical psychology, the latter sounding very much like psychiatry. The Binet-Simon measuring scale for intelligence, the production of two French psychologists, since its advent in this country has lent new impetus to the study of the feeble-minded and delinquent and at once furnished a new field which has attracted many workers. One of the results of this field of endeavor has been considerable overlapping of the psychologist and the psychiatrist, or as some would have it an overstepping on the part of the psychologist into the domain of medicine. If such has been the case the psychologist is not to blame as there has been no one else to do the work. However, the situation has created a demand for the psychiatrist with training in laboratory and applied psychology, such a physician being far better equipped to meet the needs of the situation than the psychologist with no medical training. The study of the feeble-minded and the delinquent seems to offer common ground for both the psychiatrist and the psychologist, but the latter's particular domain lies in experimental and laboratory psychology, while clinical work with the mentally abnormal and subnormal, whether they be found in the school, dispensary, or hospital should be the province of the psychiatrist. The spectacle of the non-medical psychiatrist making a medical diagnosis and suggesting treatment should never again be witnessed. The situation calls loudly for a new brand of psychiatrist with sufficient training in applied laboratory psychology to apply intelligence tests intelligently and be able to analyze and interpret the findings in the light of which remedial measures and suitable occupation may be supplied.

Occupational diagnosis, as it is carried on to-day in a few factories and other industrial corporations, seems to be more properly the sphere of the psychologist, although the need of medical training is often manifested even here, but occupational diagnosis among the subnormal is the function of the psychologically trained psychiatrist.

The school systems are gradually appreciating the need of particular care for the backward and deviate child, and we are on the eve of a rather widespread imitation of the Child Study Bureau of the Chicago Board of Education. Progress seems slow, however, when we realize that this particular bureau has been in existence twenty years. The value of such work in placing the child in the proper special class or school cannot be overestimated, if indeed, the bureau was not the active agent in obtaining this special means of training. Then, too, such a bureau can quickly detect the feeble-minded. It is now generally appreciated that it is best for the child and most economical for the State that this condition, if present, should be discovered early in the school course. Such a child should be registered or recorded as feeble-minded, and never lost sight of. With the proper supervision applied the State would be saved great sums now required for police, penal, and custodial institutions and the reproduction of the feeble-minded would be greatly diminished.

The discovery of the moron and the realization of the economic loss that is entailed through the antisocial conduct of this class is [illegible] grounds of suggestion credit. The matter. The problem of the "corrective" institutions, "rescue" homes, and "industrial" schools is in the majority of cases the problem of the moron, although not very frequently recognized as such. Indeed, this class of trouble makers even to-day goes generally unrecognized. From judges on the bench down to the ordinary layman there is a startling need for education and appreciation of what these subnormals do and do not do.

The recent work of Stearns and Rossy in the Massachusetts State Prison shows what a large percentage of the convicts (22 per cent. in the first 300 prisoners examined) are definitely morons, and in addition there are 11 per cent. "borderline" cases. These figures point the way. There is no question that when the moron is better understood a new criminology will be written. At present the law takes no cognizance of and makes no provision for him. Goddard's book, "The Criminal Imbecile," will arouse great interest as it shows how important is the psychiatric examination of the antisocial. Already a few courts have made such provision, notably the Chicago Municipal Courts where Judge Olson several years ago established a psychopathic laboratory in which suspected cases may be examined prior to trial. There is not the slightest doubt that Judge Olson's far-sighted innovation will be copied in all large courts throughout the land. In the domestic relations court particularly are the services of a psychiatrist required. Probably in no other court does disease of the central nervous system occur with greater frequency. Alcoholic psychosis, paranoias, and feeble-mindedness are the common types witnessed, and the spectacle of a husband suffering from one or the other of these being sent to jail or the House of Correction on non-support charges is frequently seen.

The day will come and it may not be far off when the law will make it impossible for the feeble-minded and unfit to mate legally, and in determining who shall and who shall not marry the services of the psychiatrist will be indispensable. Not only will a new criminology be written but a new penology. Each year shows a greater use of the indeterminate sentence and an intelligent application of this measure means a thorough study of each case and this requires adequate history-taking, a social investigation, and medical survey, the most important part of the latter being the psychiatric examination.

The problem of the delinquent boy and girl generally speaking is very imperfectly understood. In the attempt at solution many juvenile courts have been established in this country, but only those which have provided for psychiatric and medical examination can approach adequate results and these are very few and far between. Good examples of what should be done in detention examination

and study are the Juvenile Psychopathic Institute of the Chicago Juvenile Court and the Detention House of the Philadelphia Court. The lack of proper handling in the juvenile court is responsible not only for the "repeater" there, but elsewhere. Wherever found the delinquent boy or girl should [illegible] benefit of a medical and psychiatric survey and largely by the results thereof should the question as to permanent detention be determined. This assumes that the necessary laws for such a course are on the books. As a matter of fact, however, very few States make any provision for the permanent detention of the defective, the new Illinois law being a notable exception. Massachusetts has a law but it has not been enforced. As conditions are now almost universally the delinquent is not in custody, no effort being made to determine his mentality, he is turned out among the people at 21, just the age when most antisocial difficulties begin; and even if it is known that he is feeble-minded, in many States nothing else can be done at the upper age limit, for admission to institutions for feeble-minded is usually much under this. For instance, it is 16 in Maryland—can there be anything more absurd? Just at the time when the feeble-minded girl becomes most dangerous to society through her liability to propagate feeble-mindedness, she either cannot be segregated or if she happens to be in a custodial institution she cannot be detained.

A prominent social worker the other day said, "I believe nearly all our cases are more or less 'borderline' and subjects for psychiatric study." The work of the Mental Hygiene Society in Baltimore during the last three years shows how true this is. The society cooperates with all the charity organizations and employs a psychiatrist who is at their call. The advantages gained thereby in suggesting a solution and treating the case have met with widespread appreciation, and the mental survey has become an indispensable part of charity work. The financial saving to the community pocketbook is a very large item, but is secondary to the importance of helping formulate community plans for prevention of inefficiency, mental disease and feeble-mindedness. The study of the vagrant, the petty offender, the sexual delinquent, and many other types and combinations made possible only by the cooperation of many agencies will no doubt be duplicated elsewhere, and whether carried on in similar or modified methods, offers a large and new field for the psychiater.

There is probably no branch of medicine which has made greater strides into prominence than psychiatry. Within a few years, from the obscurity of institutional isolation it has emerged to become of widespread value and application in the community. The future seems to promise an even greater field of usefulness.

New Clinical Form of Tetanus.—Bérard and Lumière report the existence of a so-called cerebral tetanus in which cerebral symptoms are slow to develop—from one to two weeks after the appearance of the contractures. These consist of hallucinations, delirium, agitation and a phobic state and last at least eight days, after which there is a slow involution. The form is apyretic.—*Bulletin de l'Académie de Médecine.*

Medicolegal Notes.

Employer's Implied Promise to Pay for Medical Services to Servant.—In an action on an employer's implied promise to pay for medical services rendered his servant, the Alabama Supreme Court held that the evidence, consisting largely of detailed conversations between divers persons and the defendant, was sufficient to warrant the trial court, sitting as a jury, in drawing the inference of assent or agreement on the part of the employer to liability for necessary and reasonable medical attention to the injured man. The court quoted Curry v. Shelby, 90 Ala. 277, 7 So. 922, as follows: "Though the evidence is not conflicting, it is oral, and manifestly inferences are to drawn therefrom upon consideration of all the facts and circumstances. Every person who may go for the regular attending physician when needed by his patient, or who, from considerations of friendship or humanity, may require him not to discontinue his attendance, does not render himself responsible for the services of the physician. Whether he does or not depends upon the attendant circumstances. However well satisfied the court may be as to the proper inferences, if there be any evidence, however weak, from which an adverse inference may be drawn, the case cannot properly be taken from the jury. * * * Both express and implied contracts are founded upon the actual intention and agreement of the parties; the only distinction between them being as to the mode of proof, or evidence by which they are substantiated. * * * There are, no doubt, some cases so free from ambiguity or opportunity for inference, as that the court itself could legally presume such intention; but in all cases of doubt, it is well settled to be a matter proper for the determination of the jury, who would have a right to consider all the relevant circumstances of the case throwing any light upon the question of such intention." If the services were rendered by the plaintiff on the sole credit of the defendant, the promise of the latter was held original, and without the statute of frauds. Judgment for the plaintiff was affirmed.—Weil v. Centerfit, Alabama Supreme Court, 78 So. 885.

Question of Proper Care for Patient Held for Jury.—In an action to recover damages for alleged negligence on the part of a physician in failing to give proper attention to a patient it appeared that the defendant was employed by the plaintiff, the father, to attend his child, five years old. Evidence was produced to the effect that the defendant called as requested the first time, and, after rubbing his hand across the back of the child and taking him by the arm, diagnosed the disease as scarlet fever. No other examination was made, nor were instructions given as to the care to be given the child, except that some pills were left with the mother to administer, with directions to bathe the child frequently. Witnesses also testified that the day following the first visit of the physician he was requested to call and see the child again; that he failed to do so, making the statement that the disease must run its course; that on the next day he was called upon to visit the child in the morning, in the afternoon and in the evening, and on each occasion declined to make the visit, but later, after urgent request, came to the house, the child dying shortly after his arrival. There was also testimony to the effect that the defendant expressed regret for not having visited the child when first called that day, and in effect admitted that had he done so the child's life might perhaps have been saved. The defendant introduced testimony contradicting specifically and in detail every material matter relied upon by the plaintiff for recovery, thus making issues of fact, the determination of which by the jury the appellate court refused to disturb. The questions whether the defendant gave the case the attention necessary and proper under the circumstances and also whether such negligence, if such existed, was the proximate cause of the patient's death, were also held for the jury. The court held the evidence sufficient to show that the defendant made no effort to inform himself of the condition of the patient or of the progress of the disease. There was no claim that the defendant did not possess skill, knowledge and experience in his profession, or that he made an error in diagnosing the ailment.—Tadlock v. Lloyd, Colorado Supreme Court, 173 Pac. 200.

Military Medicine.

THE "BIG PAROTIDS" OF THE SOLDIER AT THE FRONT.

Under this title Mattei describes in *La Presse Médicale* for June 13 a condition which may be termed false mumps. Of the total number evacuated for mumps, 40 per cent., he says, are genuine cases. The remainder comprise cases of parotitis, which occur as complications of various infectious diseases other than mumps, such as typhoid fever, scarlatina, and icterohemorrhagic spirochetosis. These cases make up about 10 per cent. of the total. There now remain 50 per cent. of cases which are not infectious nor dependent on any constitutional condition. In other words, they suffer only from enlarged parotids. The organs are enlarged and lobulated. There are no adhesions, there is no pain, the function of the lower jaw is not compromised. The other salivary glands do not participate. The history shows clearly that the process begins insidiously. As a rule, the cases duplicate one another closely, and only in a few was there anything like a casual factor brought out; thus one patient had had measles, but not until after he had noticed the enlargement. Another patient noted the coincidence of the engorgement of the glands with an emetine cure of chronic dysentery. The fifty men were not long away from their commands. The lesions are believed to represent a hypertrophic sclerosis of quite unknown origin. Most of the victims were over 30 years of age. Orchitis was never seen, before or after the enlargement. It is known, Mattei says, that certain Asiatics are subject in the spring of the year to similar swellings which have no apparent cause, and such enlargement may be of the same nature as the one under consideration.

This article is interesting in connection with an investigation previously made by Capt. D. W. Wynkoop, M. R. C., regarding the prevalence of pseudo-mumps among the Indo-Chinese laborers in France. The results of this investigation were embodied in a report by Captain Wynkoop dated June 1, substantially as follows:

Mumps seem to be a disease indigenous with all of the Indo-Chinese, and it would appear to be a most common condition with them, occurring in the same individual in many cases every year. It is looked upon as being contagious by some, but others consider it a natural occurrence.

With the Indo-Chinese the inflammation of the parotid gland produces greater sensitiveness than that found in similar diseases among our own race. They shrink from the lightest touch of finger, although under ordinary conditions they are moderately stoical to pain. The swelling of the gland is small in comparison with mumps found among Europeans. In many cases at the camp at Chaluy (580 laborers) the swelling of the gland subsided in twenty-four hours from onset. In returning cases from the French Hospital for Infectious Diseases with corrected diagnosis of "no mumps," the French surgeon there made the statement that in his experience with this race in their own country a diagnosis of true mumps could not be made until after the parotid gland had shown its inflammatory condition for three days. In his own experience, Captain Wynkoop discovered that after one local application of iodine painted over the inflamed part, the swelling entirely subsided within a day or two. Anatomically the gland is always in evidence in the Indo-Chinese regardless of health. This is contrary to what is noted regarding the parotids of many of our own race. Constitutional disturbances are practically nil with this swelling of the parotid in the Indo-Chinese. It does not appear to be contagious in this mild disappearing form.

If there is a pseudo form of this disease, and this ideopathetic form of mumps among the Indo-Chinese is such as described, it would be useless to overburden our hospitals with them, Dr. Wynkoop believes. During his service at this Indo-Chinese labor camp at Chaluy he saw but three cases of orchitis (all non-traumatic or gonorrheal), but they had no apparent relation with the parotid gland. In connection with suspected cases of mumps, a delay of at least three days might be made before an elaborate diagnosis, and they should not be sent to a hospital, nor should any attempt be made to isolate them during this time. The treatment suggested by Captain Wynkoop would be a local application of tincture of iodine and a dose of castor oil.

REEDUCATION OF THE BLIND SOLDIER.

"The ophthalmologist is the typhlophile par excellence," said a French specialist in 1902, and since the war began the ophthalmologists of France have made this saying good. Since 1916 a periodical has been devoted to the welfare of the eye-wounded soldier (*Journal des blessés aux yeux*). In *Le Progrès Médical* for June 8, Ginestous asks when should reeducation begin. The answer is, "at once, while the soldier is still in the hospital." Small workshops for the blind are recommended for the vicinity of the various ophthalmological centers, and the soldier even if not hopelessly blind should prepare himself for the worst. Absolutely nothing is risked by this course, while much may be gained. In these little studios and workshops he at once learns reading and writing as well as some trade like brush making. He also has his diversions and pastimes. Ginestous has had much experience in the Eye Center at Angers. Every one of his patients has been able to read and write and the ease of learning these accomplishments is remarkable. Each one has begun some gainful occupation and is ready for the special institutions for reeducation. At Bordeaux, Professor Lagrange has had a like experience. Not only the hopelessly blinded but those threatened with blindness master their Braille and receive their initial training in carpet weaving, brush making, new soling of shoes, small gardening, etc. Reading and writing are among the great consolations of the blind and the Braille system holds its own against all innovations. Intellectual culture enables him to turn his misfortune to good account by becoming learned in many subjects which with vision retained would perhaps never have appealed to him. In the Lescure school for reeducation French classics are studied, especially those which relate to chivalry. It is held in some capable quarters that a blinded man must by all means continue at his occupation when this is in any way practicable.

In his professional labors the blind is not inferior to the seeing man in quality but is behind the latter in output, which handicaps him in supporting himself. It is well for him to have at least two occupations. The latter naturally fall under two heads: first, tried occupations, which have been proved successful for many blind men, and second, untested callings in which individual success might or might not be possible. Under the first head come time-honored trades like brush making, which are universally taught in schools for the blind. If, however, there are 2000 blind soldiers to look out for, all should not be made brush makers. Two other occupations almost as common for the blind are chair caning and basket weaving, which are better in rural districts than brush making. But none of these occupations is lucrative enough for a blind man—at most 2 or perhaps 3 francs a day is the limit of income from this source. A blind cobbler can resole two pairs of shoes daily, which gains his livelihood. The cooper's trade requires 12 to 18 months' apprenticeship, but the daily income varies from 6 to 10 francs—quite respectable. An excellent outlook is also present in agricultural activities.

American Army Makes Health Records.—For the week ended July 26 the combined reports of the American Expeditionary Forces and the troops stationed in the United States show an annual death rate from disease of 1.9 per thousand. The rate for men of military age in civil life is 6.7. This rate is based on an approximate strength of 2,500,000, and includes men living under abnormal conditions, the overseas record being made while the men were fighting in the Marne salient when they were frequently compelled to eat and sleep under the most primitive conditions. During the Mexican War the annual death rate from disease was 100 per 1,000; during the Civil War the rate, in 1862, was 40 per 1,000; in 1863, it was 60 per 1,000. The rate for the Spanish-American War was 25 per 1,000. The lowest figures heretofore recorded was 20 per 1,000 during the Russo-Japanese War.

Hospital for Shell Shock.—A base hospital for the treatment of shell shock has been established at a chateau in Lorraine to which American soldiers suffering from shell shock are hurried in the shortest possible time after the symptoms of this condition appear. A special ambulance service has been organized which makes an effort to get the shocked soldiers to the hospital within forty-eight hours after symptoms are manifested, since it has been found that many cases are curable if they come under treatment at this early date.

Correspondence School for Pharmacists.—A correspondence school for naval pharmacists is being conducted by the Bureau of Medicine and Surgery of the Navy, the course being in charge of Surgeon Henry L. Dollard, U. S. N. The benefits of the school are available to all pharmacists and chief pharmacists, permanent, temporary, and of the reserve. The course is so conducted that every pharmacist taking it gets the benefit of the experience of the other students.

Still More Nurses Needed.—Surgeon-General Gorgas announces that 50,000 nurses will be needed by July 1, 1919, to assist in the care of the sick and wounded of the American Army. Young women whose husbands are fighting in France will be accepted as hospital aids, but the vast majority of the 50,000 women must be trained nurses and available for overseas service. Fully 15,000 women can be used as hospital assistants in the United States.

Course for Laboratory Aids.—A special three months' course at the New York University and Bellevue Hospital Medical College has been arranged for those who wish to qualify as laboratory assistants in bacteriological work for immediate service in the camps and hospitals. The course is arranged by Dr. William H. Park, Director of the Laboratories of the New York Health Department, and Dr. Anna M. Williams, Assistant Director. It will open September 4.

Typhoid Fever Among Interned Germans.—Four hundred well-defined cases of typhoid fever have developed among 2,200 interned German merchant sailors at Hot Springs and other cases are under observation. Military authorities in charge have asked the aid of the United States Government in providing hospital care.

Red Cross Aids Many Hospitals.—The hospital supply service of the American Red Cross in France is providing surgical instruments, equipment, drugs, bedding, clothing, and amusement for 4,361 hospitals in 1,500 places in France. More than 12,600,000 articles were packed and shipped from the distributing station in Paris since January, 1915.

Grand Central Palace to Be War Hospital.—It is reported that negotiations are under way looking to the taking over of the Grand Central Palace, in New York City, for a war hospital. Certain of the tenants state that they have been told that they must give up their leases and prepare to vacate by September 15. The building has twelve floors, each having a floor space of 30,000 square feet.

Attacks on Hospitals Continue.—A despatch from the American Army on the Vesle Front states that on August 17 German bombarding machines made two separate attacks upon an American field hospital south of the Vesle, but were driven off by the Allied air-craft guns. There were no casualties.

Perfection of Plans for Care of Wounded.—A resumé of the great machine that has been created in this country for the reception and care of our wounded men from overseas shows that the normal hospital capacity for the care of wounded men at the end of a year's preparation is 90,095 and the maximum capacity 99,243. This includes the capacity of general, base, embarkation, and debarkation hospitals. It is expected that within a few weeks the first of the seriously wounded whose injuries will incapacitate them for further military service will arrive in New York. Mobilized and ready to minister to the needs of these soldiers are 529 officers of the medical, sanitary, and dental corps, 2,649 trained hospital attendants, ambulance drivers, and other enlisted men of the Medical Service, 342 graduate army nurses, and 65 civilian helpers. The general plan of handling

the men as they arrive, which is under the direction of Colonel James F. Kennedy, is to transfer the men as soon as possible to one of the three debarkation hospitals, one of which is at Ellis Island, the other two being the Fox Hills Hospital on Staten Island, and the hospital located in the old Greenhut department store building. From the debarkation hospitals the men are transferred to the receiving hospitals of which three are now ready. At the earliest moment consistent with proper care and treatment the men will be sent from the receiving hospitals to the proper reconstruction hospitals, usually to the institution nearest the home of the patient. For the transportation of wounded men in New York City the Medical Corps has organized a fleet of six hospital boats. Picked crews man these ships and the Red Cross has supplied the nurses. The hospital trains for transportation to distant hospitals consist of ten cars each, and represent the latest word in railroad construction. In all there are about eighty hospitals engaged in the care of soldiers and sailors. The enormous expansion that has taken place in hospital facilities during the past year can be appreciated when the fact is taken into consideration that the normal capacity of the general hospitals which are to receive the overseas patients is 14,733 beds, and the emergency capacity is 17,447 beds. Additional general hospital construction now under way will add 7,027 beds to these totals of over 90,000 beds. These figures do not include the accommodation furnished for convalescent soldiers and sailors in the homes that have been turned over to the Government to be used as convalescent hospitals for the duration of the war and as long after as they shall be needed.

Neustadter Convalescent Home for Government.—The construction of the convalescent home in South Yonkers, which is provided for under the will of Mrs. Caroline Neustadter by a fund of $1,000,000, will be started within a few weeks. The building will cost $250,000, and will be located at the corner of McLean Avenue and Central Road, South Yonkers. The trustees plan to make it a fitting testimonial to the philanthropy of the donor by offering the building when completed and fully equipped to the Government for use as a hospital for officers. Although the plans provide for the accommodation of 75 patients, the building can be turned into a hospital of much greater capacity.

Convalescent Hospital Opened.—The new $2,000,000 convalescent hospital at Colonia, N. J., for wounded men from overseas and for invalids from army cantonments in this country is now ready to receive patients. The site of the hospital is the estate of Charles D. Freeman, who has leased his land and his house to the Government for $1 a year. Seventy-two buildings have been erected since February 2, which provide accommodations for 1,607 patients, 160 nurses, and a medical corps numbering 550 men. Reconstruction work will play an important part in the program of the institution. Lieutenant-Colonel Alfred P. Upshur, M. C., U. S. A., is in charge and Major Fred H. Albee is to have charge of the surgical work.

New Training Schools for Nurses.—A new training school for nurses is to be opened in September as an adjunct to Base Hospital No. 1, The Bronx. The first training school established by the War Department in connection with base hospitals in this country is at Spartansburg and a third will soon be opened in connection with the United States Debarkation Hospital at Fox Hills, Staten Island.

A Third Unit for Women's Overseas Hospitals.—At the request of the French Government a third unit of the Women's Overseas Hospitals, which is to specialize in the handling of gas cases, has been started for France by the National Woman Suffrage Association. Dr. Marie Louise Lafort of New York City is to be at the head of the gas hospital. Her associates on the staff will be Dr. Adab McMahon of Lafayette, Ind., Dr. Irene Morse of Clinton, Mass., Dr. Elizabeth Bruyn of Brooklyn, Dr. Alice Flood of New York City, and Miss Clara Paquet of the New York State Board of Charities. The hospital is to be a mobile unit with a capacity of 300 beds. One ambulance has been donated to the unit by the children of the Cortelyou School, and another by the Sorosis Club of Brooklyn.

German Agents Sell Narcotic Drugs to Soldiers.—Reports of surgeons in widely separated army camps of the use of habit-forming drugs have led to a Federal investigation which reveals a concerted attempt by German agents to supply soldiers in army cantonments with habit-forming drugs. Two arrests have been made and more are to follow. According to the Federal authorities these drugs have been sold at surprisingly low prices.

Lieutenant Max Philip Cowett, interne and house physician at Bellevue Hospital, New York City, from 1915 to 1917, has been awarded the Croix de Guerre by the French Government for gallant work in the trenches.

Deaths in the Service.—Lieutenant David Robertson, M. C., a graduate of Edinburgh University and a surgeon in the United States Army almost continuously since the beginning of the Civil War, died in his quarters on Governors Island, on August 15, aged 87 years. Lieutenant Robertson was on the retired list but reentered the Medical Corps upon the entry of this country into the present war.

Major David Everett Wheeler, M. R. C., U. S. A., of Buffalo, was killed during the allied counter offensive on August 13 while attending the wounded under fire. He was a graduate of the College of Physicians and Surgeons, New York, in 1898, and was 46 years of age. Major Wheeler went to Europe during the first year of the war as a Red Cross worker. He enlisted in the Foreign Legion as a soldier on February 15, 1917. In the Champagne fighting, on September 28, 1918, he was wounded in the right leg, and while trying to crawl to the rear stopped to attend to wounded and suffering men about him. For this he was awarded the French War Cross. He later joined the Canadian Army, receiving the rank of Captain. When the United States entered the war he was transferred to the American Forces. He served as Regimental Surgeon in Lorraine, at Cantigny, and Chateau Thierry.

AN EPIDEMIC OF THREE-DAY FEVER IN EUROPE.

PROFESSOR SAMPIETRO, writing in the *Annali d'Igiene* on the so-called Spanish influenza, which is now recognizable throughout Europe, believes that it is nothing more or less than three-day fever. The Spanish medical men have variously pronounced their epidemic influenza, dengue, three-day fever, pappataci fever, and trench fever. Our real knowledge of three-day fever goes back only to 1909, when it was studied in Dalmatia and Herzegovina. An old popular designation was "dog sickness," because the prostrated patient was thought to resemble a dog during very hot weather. Another name was "Dalmatian fever." The latter was not exactly new along the Mediterranean, for such designations as "summer fever," "summer influenza," exist in popular language. Even the expression three-day fever appears to have been an old one resurrected. All of these and other terms were purely military rather than civil, showing that the troops were those who chiefly suffered from the visitation. The term barrack fever has even been used when the affection has occurred in barrack life. As far back as 1888 Saggini, a military physician, called the attention of his superiors to this type of fever. Numerous descriptions of three-day fever show a notable resemblance to the present epidemic, but there are unexplained differences. For example, the Spanish epidemic was most certainly a four or five-day fever, and there has been nothing adduced to show that it is insect borne. Three-day fever, on the other hand, is believed to be transmissible by the sand fly, *Phlebotomus pappatasii*, and to be the same as the pappataci fever. The latter occurs in the three-day fever belt but is by no means limited to it. As a distinct affection pappataci fever has been regarded as very like dengue, but without exanthem. In recent years the three affections seem to have been badly confused, especially on the Oriental front. Castellani has seen a two-day or three-day fever in the Orient, in which an exanthem was present, and which he believed to be transmitted by a species of phlebotomus.

To uphold his contention that the Spanish epidemic is three-day fever Sampietro has his work cut out for him. He asserts somewhat against the evidence that the latter is of two or three days' duration—or at least that the high temperature does not last beyond that time, and he also contends that the Spanish disease is not influenza as we know it. In order to show that insects play at least a partial rôle in its transmission he seems to rise again above the level of facts, for it has been definitely stated by a Madrid physician that insects have been excluded in this connection. Recently it has been shown that the phlebotomus exists in parts of Spain and the appearance of the epidemic late in May can harmonize with the hypothesis of insect transmission, and therefore the author thinks that it remains only to connect the Spanish epidemic with the fly, which may escape observation in part because of its minute size.

THE OPERATIVE TREATMENT OF CANCER.

NOT only professional statisticians but learned physicians themselves have deplored the fact that men of our profession, failing to realize that statistics is in itself a profession, do not hesitate to draw the most varied conclusions from their amateur efforts along these lines. Even the figures of Hoffman on the increase of cancer, which may be supposed to have the force of actuarial computations, have been attacked on one ground or another, in so far as they are alleged to connote this increase. For example, it is said by a professed statistician that in all countries with alleged low incidence of cancer there is a paucity of physicians—the fewer the cancer deaths per population unit the fewer the number of medical practitioners per unit of population to make diagnoses and report deaths. This fact invalidates the argument of increase of cancer almost *in toto*, for the adherents of the cancer increase theory assert that the increase is due to the increase of per capita wealth and luxury. Unless it can be shown that the inhabitants of certain backward countries do *not* die of cancer but of other affections the entire argument falls to the ground.

In the *Correspondenz-Blatt für Schweizer Aerzte* for June 22, Dr. Aeby shows by statistics that the knife does not cure cancer and that the sufferers from that disease live practically as long, although not longer, if they are not subjected to operation. He is a former student of Professor Krehl, than whom there is no greater contemner of amateurish medical statistics. His figures were limited to cancer of a special locality, as the female breast or cervix uteri. As a rule the tenure of life is reckoned from the time that operation is performed, or refused, but according to Aeby there is a source of fallacy here, for the term of life must date from the time of first recognition of the disease. Of several ways in which survival may be computed the following seems least open to objection. One starts, as already stated, with the first appearance of the disease and computes the percentage alive after successive intervals. Thus one-eighth of a year later 100 per cent. were alive irrespective of whether an

operation was performed or not, although at so early a period it is not likely that any were submitted to operation. One-quarter of a year after first recognition 100 per cent. of the unoperated were living but only 95 per cent. of the operated. This would ordinarily be explained by primary operative mortality. From one-eighth year to fifteen months the survivors at each three months' interval were more numerous among the unoperated; but at this juncture the operated subjects took a slight lead, only to lose it again after two and a half years. At four years' total duration the operated subjects regained the lead and held it, but by this time the percentage of survivors among the operated had also dwindled almost to the vanishing point. When the two curves are plotted together, the complete lack of superiority of operated over unoperated is only too apparent and the margin of survivors after operation is so small as to be quite insignificant.

Certainly no partisan of the knife would have expected such an anticlimax. It is of course true that in the clinic we are not governed by the results of statistics but by the need of doing something to rid the patient of distressing symptoms. We are not to suppose that the author is seeking to discourage operation in the individual case. It is, however, certain that the knife will never relieve the community as a whole of its cancer, no matter how early the diagnosis or how experienced the operator. Space does not permit of an analysis of these figures in order to detect the fallacy in the usual method of computation. The figures may be supposed to speak for themselves and agree with those of Krönig, who found that but 5 per cent. of his cancer subjects were alive after the lapse of ten years following operation—a conclusion which has led him to abandon the knife in favor of radium and *x*-rays.

ACTION OF SUGAR ON THE SPUTUM IN TUBERCULOSIS.

The recently published experience of Professor Lo Monaco regarding the action of cane sugar on the bronchial secretion has led Lucherini to make a trial of the remedy in the tuberculous (*Giornale di medicina militare*, May 31). Lo Monaco has worked on this problem since 1914 and has shown that injections of carbohydrates activate many of the secretions. His results have been amplified by other men. Thus while small doses increase the amount of milk in nursing women, large ones produce the opposite action. These injections have also been shown to possess hemostatic powers. The local action of saccharose on wounds is believed to be due to vasoconstrictor action.

The author's work consisted in studying the influence of injections of sugar on the bronchial secretions of consumptives and upon the principal symptoms of the disease. We know from the work of Berendes in 1910 that injections of 5 to 7 per cent. aqueous solutions of saccharose are well tolerated. The first patient was under observation for several days before the injections were begun. His sputum had ranged in amount from 10 to 20 c.c. in 24 hours. After the first injection it increased until on a number of days it reached 30 c.c. and was never below 20. He received one daily injection. After six days of increased sputum there was a sudden drop to 8, 10, 5 c.c., etc., the daily injections being maintained. The frequency of the injections was now somewhat abated and the daily amount of sputum showed a certain average increase, but after resumption of the daily schedule the amount lessened and then ceased outright. During this period local conditions were unchanged, fever showed no decline, cough was lessened, but there was a little improvement in the night sweats and general condition. The arrest of expectoration was the one striking feature of the experiment. The second patient raised from 80 to 130 c.c. sputum daily. Under a prolonged course of daily injections the amount was decreased to from 50 to 90 c.c. On the day following that in which the injections were first intermitted the quantity increased to 110 c.c. Daily injections were at once renewed and the amount again fell to from 50 to 90 c.c. Numerous other consumptives were treated, including one who raised about 100 c.c. daily. This patient at first showed improvement, but despite injections his sputum increased on certain days to 210, 220, 270 c.c., etc., although on odd days the average was low. After suspension, his amounts ran up to 400, 500, and above. The sugar seems to have retarded the expectoration, but to no purpose.

Medicine and Democracy.

It is not easy, at first sight, to appreciate a relationship between medicine and democracy. However, upon closer consideration it would seem that of late years the practice of medicine has been greatly revolutionized in some countries. And curiously enough, this change began in Germany, one of the most autocratic of lands. The system of providing medical treatment for the poor at a very small cost was inaugurated by that most undemocratic of countries, and moreover was made law not from democratic but from exactly opposite motives. A similar system has been put into force in Great Britain, in this instance with the support of public opinion, without which the enactment of laws is impossible in that country. These schemes of a like nature providing for a cheap medical service have been brought into vogue recently in a strictly autocratically ruled country and in an essentially democratic land, the motive in Germany being by making the people beholden to the State to keep them in subjection to the powers that be and in Great Britain the system was brought about by a radical government anxious to promote good health in the community and incidentally, perhaps, to earn the good will and votes of the people benefited. Democratic countries, generally speaking, appear to be averse to any kind of State aid, be it medical or otherwise. For example, the obviously democratic countries, the United States and Canada, have up to the present held themselves aloof from plans

whereby the poorer parts of the population shall have the right to demand free medical or surgical attention or, at any rate, such attention at a small cost. While there is much to be said on both sides of the question, it is undoubtedly a fact that there are certain diseases which cannot be stamped out unless there is earnest cooperation between the public and the medical profession, and unless, also, means are taken to educate the population as to the gravity and nature of these diseases and if necessary to enforce laws to ensure prevention and treatment. The venereal diseases are the most conspicuous examples in point, and it is being impressed upon the minds of medical men and legislators that the only way by which these infections can be exterminated or checked is by the enforcement of laws. In evolving schemes by which disease may be prevented and more certainly cured, care must be taken to avoid too great paternalism as in Germany. Plans based on democratic principles must be formulated and the medical profession must retain its independence.

Hooverizing Hot Water.

It is an old truism that there is nothing of which we are so unconscious as water and nothing we miss so greatly when deprived of it. As the flat-dweller of the present era turns on his hot water luxuriously no image crosses his mind of men staggering across deserts in pursuit of mirages, or of our immediate forefathers, only a generation back, with their laborious heating of dishpans over the stove for the periodical bath. The present war, however, has made us realize that back of all the luxury of the present time are expense and waste and that a dispensing with some of what we have been taught to call necessities might be beneficial to health as well as pocket-book. An English writer, Dr. Gerald W. Maw, believes that the too lavish use of hot water for bathing is a practice to be deplored, not only on account of the waste of fuel which it implies, but also for hygienic reasons. The immediate effect of a hot-water bath is a relaxation—a pleasant feeling of warmth and lassitude. There is a great temptation to remain much longer than is necessary in the tub. Very easily the daily bath can be prolonged until ten, fifteen, or even twenty minutes are spent immersed in hot water, enjoying the luxurious feeling of relaxation. Unfortunately, however, there is no corresponding reaction and inevitably persistence in such habits must result in loss of tone. Soon the individual begins feeling tired and has difficulty in accomplishing the daily tasks. There is a lessening, too, of resistance to infection. The present then, with its economies and sacrifices in every direction, is a good time to educate the public to correct and helpful habits. A cold bath in the mornings for those whom it benefits and a tepid bath two or three evenings a week will be the program for the average person rather than the somewhat Oriental indulgence in hot water *ad libitum*. Not only will the physical condition of the patient be greatly improved under this regime, but the doctor will be doing his bit toward preserving the coal supply and preventing heatless days and nights next winter.

Chinese Immigration in Mexico

The Mexican Bulletin of Public Health for May 31 protests vigorously against the continued immigration of Chinese into that country. It demands either abolition or restriction of this movement of race. The memorial, which is signed by Valenzuela, chief of the disinfection service of the department, is dated April 3, 1918, and begins with a reference to the classical period of the world's history, when the peoples were intelligently striving to keep intact the purity of racial sources. This feeling was an instinctive one of self-preservation. The great biologists of the nineteenth century gave to this sentiment a scientific backing. They showed how races may deteriorate and how such deterioration may be antagonized. The science of human breeding had its beginnings. But the artificial selection applied by breeders cannot be transferred to mankind. Freedom of sexual choice flourishes in the human species and is but feebly checked by laws against mixed marriages. The author appears to dread sexual contact between the Mexicans and Chinese. A number of countries have preceded Mexico in excluding the latter from citizenship and equality with the natives. From its geographical and climatic situation, its great variety in altitude and productions, its lure to emigrants from all countries, its absence of restrictive laws, Mexico has become a dumping ground for the offscourings of the earth. Mixture of blood has already gone on without the least check. Invalids, idiots, anarchists, criminals—all of these undesirables have been made welcome and have married. Valenzuela says it is now time to call a halt. As in the past, Mexico is still menaced by an indefinite immigration of Cantonese who can subsist where the native would perish, but who also know how to employ intensive methods to productive soil and who are bound to win out in either case. This immigrant can bring with him cholera, bubonic plague, beriberi, and trachoma. He mixes freely with the Mexican women, for he does not bring his own females in anything approximating a sex ratio. Of all of the evils, the author appears to regard miscegenation as the worst for the remote future; for a new mixed race would be unhealthy and of low morale and ideals.

A Cancer Platform.

The weekly Bulletin of the Department of Health of the city of New York for July 27 contains an apparently official article entitled "Concerning Cancer—a Platform upon which to Unite in the Campaign of Education." This platform is composed of twenty-one planks, fifteen of which are most commendable. Thirteen of these fifteen are lifted, for the most part bodily, and without credit, from "The Cancer Problem," by Dr. William Seaman Bainbridge, published in 1914. We are particularly pleased to note that nowhere in the article is the advice given to cut into suspected neoplasms in order to get specimens for microscopic examination. This omission of the invitation to biopsy which was promulgated by a former commissioner is most heartening, and doubtless will lead the original author gladly to forgive the omission of quotation marks.

News of the Week.

"Spanish Influenza" Arrives in New York.—During the week ending August 17, three steamships from European countries have arrived at the Port of New York having aboard cases of so-called Spanish influenza. One of these vessels came from Norway, one from Scandinavia, and one from Holland. The ships were not held in quarantine as influenza is not a disease against which marine quarantine is instituted. Those aboard the ships who were suffering from influenza were transferred to the Norwegian Hospital, Brooklyn, and cultures from their throats were submitted to the Board of Health for study. The term "Spanish influenza" is, of course, a misnomer for, as we stated several weeks ago, the disease is probably identical with the influenza with which we have long been familiar in this country, and which prevailed here very extensively last spring. The Health Department has instituted a campaign against influenza and all similar communicable diseases. Every ship reporting a case of influenza will be registered with the Health Department, and Health Department inspectors will obtain from the immigration authorities the destination of the cases reported. Those remaining in this city will be located and placed under the supervision of nurses of the Health Department who will see that they receive proper treatment and are isolated when such a course seems advisable. All physicians of the five boroughs are requested to cooperate with the Health Department by reporting cases of influenza and seeing that the regulations regarding the treatment and prevention of communicable diseases are carried out. The fight against public "spitters" will be renewed. Sanitary inspectors have also been instructed to keep a close watach on all soda water fountains to see that the regulations regarding the washing of glasses are rigidly enforced.

Control of Venereal Diseases.—The Federal Government will expend during the fiscal year ending June 30, 1919, $1,000,000 in the control of venereal diseases. This sum has been made available for expenditure under regulations established by the Secretary of the Treasury, by an act of Congress approved July 9, 1918. The work will be carried out through the various State Boards of Health. The activities will include securing reports of venereal infections; control of those infected, so as to prevent further spread of the disease; establishment of free venereal clinics; suppression of vicious conditions which favor the spread of venereal infections; the carrying out of a systematic educational program for the general public as well as for those who are infected. The act gives authority for the establishment of a new division in the Bureau of the Public Health Service, to be called the Division of Venereal Diseases. Such a division has been established and a chief appointed. The act also grants authority to the Public Health Service for the regulation of the interstate travel of venereally infected persons.

Infant Mortality Rate of New York Lower.—The records of the New York Health Department show that from January 1, 1918, to date there have been 7,532 deaths of infants under one year, as compared with 7,543 for the same period last year. The infant mortality rate this year to date is 85.84, as compared with 86.42 for 1917. The week ended Aug. 10 showed 289 deaths of infants under one year of age, as compared with 313 deaths in the corresponding week of 1917. It is believed that the educational propaganda concerning the care of children is proving its efficiency.

State Hospital Pay Too Low.—In the annual report of Dr. John R. Ross, superintendent of the Dannemora State Hospital for Insane Criminals, a plea is made for a living wage for hospital attendants. It is pointed out that the problem of obtaining and retaining satisfactory hospital employees is causing vital concern and that the difficulty can only be overcome by giving adequate remuneration. The salary of hospital attendants is pitiably below that of prison guards, yet it will not be denied that equal tact and intelligence are expected of employees in an institution housing the criminal insane. Dr. Ross believes that the dearth of help in the hospital is not due to war conditions so much as to inadequate wages, and that to expect to get good service for $45 a month is not consistent.

Enlargement of the Philadelphia Roosevelt Hospital.—The sum of $300,000 is to be raised for the erection of a new building for Roosevelt Hospital in Philadelphia. The proposed structure is to be 150 feet long and 42 feet deep, five stories high, with a roof garden and basement, fireproof, with concrete floor. It will have a capaciiy of 118 beds distributed over a number of small wards. The main operating will be on the top floor and an emergency operating room in the basement. Isolation units will be placed on the first floor, a diet kitchen, three maternity wards, three children's wards, service rooms, lavatories, bath rooms on the second floor, diet kitchens, seven rooms with baths and nine single rooms and six wards on the third and fourth floors.

Hospital Appoints Woman Interne.—The Brockton (Mass.) Hospital, owing to the fact that all medical students have been immediately taken for war service by the Government, has for the first time in its hostory appointed a woman as interne. The woman is Dr. Mildred Haynes of Bennington, Vt.

New School for Crippled Children.—The School for Crippled Children, for which Mrs. Frederick S. Coolidge of New York gave her country place near Lenox, was formally opened on August 14. Mrs. Coolidge's gift includes a beautiful villa, thirty acres, and $200,000 as an endowment fund. At the opening exercises memorials to Mr. and Mrs. Albert A. Sprague, Mrs. Coolidge's parents, and to her husband, the late Dr. Frederick S. Coolidge, were unveiled.

War's Effect on Eugenics.—An Italian scientist just published a book in which he expresses the opinion that eugenically the war will cause an improvement. He says that if the war ends next year there will be in England 121 women between the ages of 24 and 44 years to every 100 men between the same ages; in 1910 the proportion was 108 to 100. In France there will be 124 women of the above ages to every 100 men. In Germany

there will be 199 women to every 100 men. His reason for asserting that this condition will lead to eugenic improvement is that every man will have a larger selection of women from which to choose and he will be likely to choose the healthiest and strongest.

Dr. William C. Fowler, for many years assistant health officer, has been appointed health officer of Washington, D. C., to succeed Dr. William C. Woodward, who was recently appointed health officer of Boston.

Dr. Frank B. Knause, Deputy Health Commissioner in charge in Brooklyn, has resigned in order to join the Medical Reserve Corps of the United States Army.

Dr. Frank J. Monaghan has been appointed Deputy Health Commissioner in charge in Brooklyn to succeed Dr. Frank B. Knause.

Dr. A. P. Richmond has been appointed city physician of Manchester, N. H., to succeed Dr. Roland J. Bennett, resigned.

Dr. Robert Howland Chase has resigned the medical superintendency of the Friends' Hospital for the Insane of Philadelphia after an incumbency of twenty-five years, and he has been succeeded by Dr. Albert C. Buckley, for many years his assistant.

Retreat for War Workers.—Mrs. S. T. Davis, Jr., has turned over her country home at Ardsley-on-Hudson to the United States officials in charge of the United States Gas Defense Plant at Long Island City as a recreation center for women employees. Owing to the urgent demand for masks the women get no vacations and can take advantage of the opportunity for rest only during week ends. If a woman employee becomes ill arrangements are made for her to recuperate there.

Athletes Not Short Lived.—Mr. C. E. Hammett, a veteran physical director, in a study published in the *Scientific Monthly*, shows that the belief that the athlete so strains his heart and lungs as seriously to affect his longevity is fallacious. He takes the men who have rowed in the Harvard crews between 1852 and 1892, and finds that out of 152 only two died of heart disease and but one of tuberculosis. These Harvard athletes were, on the whole, more successful professionally and in business than the graduates whose only aim was scholastic attainment. Similar results came of the investigation of the after careers of Yale students who won fame as members of the crew, of the baseball, football or track teams, between 1855 and 1895. Of 807 who underwent hard physical training during their college years only four developed heart disease within half a century, and two of these were between 68 and 70 years of age at the time. Another study of hard distance runners showed only three cases of injury in 167 men. Mr. Hammett states that a consular investigation of the jinrikisha men of Japan showed that in 1907 there were 1,200 such men over 55 years of age, actively in service in Tokio, most of them still strong and healthy.

The American Board for Ophthalmic Examinations.—The American Board for Ophthalmic Examinations, whose function it is to establish standards of fitness to practice ophthalmology, to investigate and prepare lists of medical schools, hospitals, and private instructors recognized as competent to give the required instructions in ophthalmology and to confer certificates upon those meeting the established standards, will hold its next examinations at the New York Eye and Ear Infirmary, New York, October 25. Further information may be had, upon request, from the, American College of Surgeons, 25 East Washington Street, Chicago, Ill.

New Club for Red Cross Nurses.—A Red Cross house for nurses passing through New York City on their way to the front will be opened early in September at 129 East Nineteenth Street, under the auspices of the New York County Chapter. At first, accommodations for but twelve nurses will be afforded. The establishment of the house was called for by Colonel J. M. Kennedy of the Medical Corps, surgeon of this embarkation port.

Obituary Notes.—Dr. LUTHER HALSEY GULICK died at South Casco, Maine, on August 13, at the age of 52 years. He was born in Honolulu, and was graduated from the New York University Medical School. He was appointed director of physical training in the public schools of New York City in 1903, remaining in this position until 1908. He was director of the Department of Child Hygiene, Russell Sage Foundation, 1907-13; president Camp Fire Girls from January, 1913, to the time of his death; editor *Physical Education Review*, 1901-03; president American Physical Education Association, 1903; vice-president Y. M. C. A. Athletic League of North America, 1903-06; Fellow New York Academy Medicine, Fellow A. A. A. S., and president Playground Association of America. He was secretary of the Public Schools Athletic League of New York, 1903-08; president Public School Physical Training Society, lecturer on school hygiene, personal hygiene, physical training and play, New York University, 1906; member Olympic Games Committee, Athens, 1906, London, 1908; United States delegate second International Congress on School Hygiene, London, 1907; received from Y. M. C. A. Training School, Springfield, Mass., degree of Master of Physical Education; consultant of Hospital for Deformities and Joint Diseases, and member of permanent committee International Congress of School Hygiene. Dr. Gulick had recently returned from a trip to France, made in the interest of the Y. M. C. A. for the purpose of making a survey of the moral environments of the American Expeditionary Forces.

Dr. WILLIAM H. LAWRENCE, a graduate of New York University Medical Department, in 1877, and a former sheriff of Union County, N. J., died at his home in Summit, N. J., on August 5.

Dr. CHARLES H. MANN died as a result of cerebral hemorrhage at Bridgeport, Pa., on August 3, at the age of 66 years. He was graduated from Jefferson Medical College in the class of 1872. He was president of the Bridgeport National Bank; at one time resident physician in the Children's Hospital of Philadelphia; Surgeon to the Norristown Hospital; a member of the Montgomery County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. FRANK HARPER ROSS, a graduate of Bellevue Hospital Medical College, in 1880, died at his home in Brooklyn on August 10, aged 62 years.

Dr. Rudolph Berendsohn, a graduate of the Long Island College Hospital, in 1881, died at his home in Brooklyn on August 16, aged 78 years.

Dr. William Houston Greene of Philadelphia died at his summer home at Wenonah, N. J., on August 8, at the age of 66 years. He was graduated from Jefferson Medical College in the class of 1873, and later became assistant to the professor of chemistry in his alma mater. In 1879 he was appointed demonstrator of chemistry in the medical department of the University of Pennsylvania, and in 1880 he became professor of chemistry in the Central High School for Boys. He was a member of the Philadelphia County Medical Society, and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Dr. Mary Anna Allen Howell died at Camden, N. J., on August 9, at the age of 71 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1891.

Correspondence.

A VOLUNTEER'S REASONS.

To the Editor of the Medical Record:

Sir:—There has recently come into my hands a letter from a young physician which it seemed to me might help some other physician to decide more readily whether he can afford or not to enter the national service. This letter was written by a doctor to his young wife, who up to that time had scarcely been willing that he take the sacrificial step which meant so much to them both.

"As time goes on, it seems to me more and more that I ought to 'get into the game,' even with the sacrifices that such a step will necessarily entail for both of us. With our youthful health and strength we ought to be able to make a new start after the war; and who can say that this crisis was not ordained to be a turning point which is to be of the greatest value in shaping our lives anew to greater and fuller usefulness. I feel quite sure, when I look over the map, that the struggle is to last a long time yet, for there is no jot or tittle of a sign that the Germans have changed their minds as to the issues at stake or as to their divine right to rule the world and ride rough shod over all civilization. After all, the whole matter is one of an uncompromising difference of ideas. We cannot convince them by argument of word, and therefore they must be convinced ultimately by argument of the sword. As much as we in America dislike to engage in legalized or wholesale murder, we are driven by the first instinct of all life, as exemplified in biology—the instinct of self-preservation—to defend ourselves and those dear to us, as well as those who shall come after us, against the common enemy, the aggressor who attacked our sacred institutions, founded by the fathers for the benefit of all mankind, and who would make a shambles of the whole universe in securing his ends. There can be no greater nor higher nor holier purpose than to go to the aid of those who are crying out amid blood and tears for the helping hand of him who can bind up their wounds and assuage the last agonizing hour. To this great purpose the medical men of America are called, not to fight with mere physical weapons, as necessary as that is for others, but to minister to the needs of those brave defenders of the faith that is in us, who are calling us, perhaps at this very hour, to 'go over into Macedonia' and help them in their pain and grief. That is my conception of my duty, and, dear girl, I believe it is yours, too, to fit yourself for the great work in a nursing school, from which you might emerge clad in the armor of strength for the fray, and with the credentials of the U. S. as your talisman. That would be so much better and finer than an R. N. now held by many who are not doing their full duty by mankind. We shall talk all this over when I see you."

Can there be a finer inscription for the tomb of him who now lies in Flanders fields? How many of us have beheld such a vision and have faced it quite as manfully?

Irving Wilson Voorhees, M.D.

New York.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE DIRECTIONS OF MEDICAL REFORM—THE RATIONING OF INVALIDS—THE OXFORD OPHTHALMOLOGICAL CONGRESS—THE SUPPLY OF DOCTORS IN THE FUTURE.

London, July 26, 1918.

The Government is being pressed in so many directions to proceed to the immediate formulation of its views in regard to a ministry of health that despite the enormous pressure of public affairs during a critical position of the world war time will probably be found for the early introduction of a bill into Parliament. It is of good omen that the public as well as the medical profession are preparing to receive this measure with deep attention, and it would seem that a real union of interests may be effected by it. The day has gone by in this country when the medical profession can resent lay assistance in medical matters, for it is recognized that, inasmuch as medicine plays an intimate part in the whole of social life, there must be many departments in that life where the lay element posseses more special information than any medical man can pretend to. But on the other hand, the day has equally gone by when the medical man is regarded by the public as a person full of traditional knowledge which may or may not stand the practical test of application to real problems—a person, moreover, who is ready to shelter himself, whenever his omniscience is called in question, behind some mysterious code of ethics called medical etiquette. Only cranks, whether with or without a medical qualification, hold either of these views, and at the present moment the British public is as ready to welcome the hearty co-operation of doctors in the institution of a ministry of health as the medical profession is willing to acknowledge that only with intelligent lay help can anything useful to the nation be placed on the statute book. That this is the popular feeling is indicated by the selection as candidates for the representation of the Labor party in the House of Commons of various medical men; the proletariat see that in medical science lies the best chance of improvement in the material conditions of life, and that on such vital questions as the housing of the poor, the prevention of widespread and common diseases, the care of the parturient mother, and the protection of infant life, the voice in Parliament

which is inspired by medical knowledge will be listened to.

In an open letter to the medical profession that veteran democratic reformer, Mr. Sidney Webb, has presented his views on the desirable relations of medicine to the State in response to the invitation by the Labor party to stand for Parliament for the University of London, where he is a professor. In a description of the ideal connection which he considers should exist between the medical profession in its various branches and the State, he suggests the institution, in association with the new ministry of health, of a statutory advisory committee composed "not of the existing bureaucracy or of the nominees of the great corporation, but of duly chosen representatives of the medical profession outside any area of Government service." The functions of such a committee, as Mr. Webb foresees them, would be to advise the officiate created by the ministry of health, and to report, with freedom from all censorship and directly to Parliament, whenever it thought fit. Now it is undoubted that a body like this would be extremely useful in keeping the lay side of any bureau fully informed on the medical side, and the fact that such a committee was only constructed for advisory or critical purposes would be no drawback if it should receive the power of direct communication with the House of Commons. There would be considerable difficulty in devising the machinery for "due representation" upon this body, but the significance of the suggestion lies in the fact that we have here the organization of a body of medical critics to deal with lay administrators, which is suggested, not by medical men or by academic circles in a university, but by a typical democrat standing for parliamentary honors as a Labor candidate. The spirit thus displayed is becoming a common one, and it would inevitably have a great effect on the national health of the future as well as on the position of the medical profession.

The Food Control Committees have received recently considerable extension of their powers in respect of the rationing of invalids. Extra rations can now be granted far more freely and the list of suitable cases for the concessions is much less closely limited. The Food Control Committees can give, in rationed proportion, additional meat, butter, margarine, milk, sugar or white flour on application in their localities, but these extra rations can only be obtained on the authority of the committees—that is to say, that the retailers of food cannot act on medical certificates alone. The medical profession is far from resenting the fact that complete discretion as to the diet of invalids has not been left in their hands; on the contrary, the demands by patients, and especially by the relatives of patients in behalf of the latter, were frequently very embarrassing. Many a doctor has felt that to order the extra rations which the patient asked for was unfair on the food supply system of the country; but while refusing to be complaisant he has felt that it is the resolve of the patient to seek medical advice in other directions if the request for indulgence is not granted. Except in the cases of extra rations for expectant or nursing mothers, the applications to the Food Control Committees must be accompanied by a certificate signed by the medical men in charge of the case, and this certificate sets out the diagnosis and specifies the minimum weekly amount of the particular foods required. There is, therefore much left to medical decision, while the ultimate responsibility is assigned to the Food Control Committees. The following are the diseases or pathological conditions in which special concessions are made in respect of *meat, butter,* and *margarine:* Active tuberculosis, diabetes, exophthalmic goiter, pernicious anemia, malignant disease, senile dyspepsia, a convalescence after severe illness, major operations, and difficult childbirths. In respect of *white flour* the Food Control Committees still hold that no ordinary disease can be held to require bread made from white flour, but a ration will be granted for the limited period of six weeks, and up to a maximum total of 14 pounds, to the following cases: Senile dyspepsia, intestinal or gastric ulceration, and chronic diarrhea. "Senile dyspepsia," by the way, is the term used to describe the form of indigestion accompanied by flatulence and often associated with chronic pulmonary or cardiac conditions among the aged. Extra rations of *sugar* cannot be granted to patients while in receipt of additional meat, butter, or margarine; while it is suggested that for the present *milk* should be ordered rather than meat.

The annual ophthalmological congress was held this month at Oxford, and, as usual, Keble College hospitably offered their beautiful buildings for the general purposes of the meeting, while the scientific sections met in the Anatomy Schools of the university. The first debate was opened by Sir William Job Collins, senior surgeon to the Royal Eye Hospital, formerly chairman of the London County Council, and now member of Parliament for Derby. Since the outbreak of war Sir William Collins has been ophthalmic surgeon to that immense war hospital, King George's Hospital, and it was fitting that he should be selected to start the proceedings upon such a topical theme as ophthalmology during the war, and in a practical and learned way he did justice to the theme. Alike on the pathological and the clinical sides, ophthalmology has made many new departures under the stimulus of new and sinister conditions, and Sir William Collins' words, which were reinforced by distinguished colleagues from the services and the colonies, showed clearly the direction in which progress has been made. Among those who took part in the proceedings were Colonel R. H. Elliot, late professor of ophthalmology in Madras University; Major H. C. Purchas of the New Zealand Medical Corps, Staff Surgeon Hanson, R. N. V. R., and Mr. Bernard Cridland, the secretary. Among important contributions to the proceedings may be mentioned a paper by Captain Percival Hay on the implantation of cartilage after evisceration of the eye, and a paper by Sir William Barrett, F. R. S., late professor of physics in the Dublin College of Science, upon "Entoptic Vision." This is a subject much neglected, at any rate to-day, by ophthalmologists, and Sir William Barrett's demonstration with the entoptoscope attracted much attention. Captain Hay's paper included a demonstration of a very neat piece of cosmetic surgery in connection with the eye. The procedure was devised recently at the Queen's Hospital, Sidney, and has given good results in cases where the ordinary methods for the adjustment of an artificial eye are impossible.

I have several times alluded to the mistaken policy

followed at the beginning of the war which led to the conscription of medical students for combatant purposes, and the complete denuding of the medical schools of all but their female or physically feeble scholars. A tabular statement has just been issued by the General Medical Council showing the number of medical students now in actual attendance at the various medical schools and in preparation for degrees or diplomas. The figures refer to the month of May, 1918, and show pretty clearly that the recent policy of allowing medical students to return to their work, if they could prove that they were seriously engaged upon it, is bearing good

fruit. That there is now, and will be for some little time, a shortage of medical practitioners cannot be denied, but in face of the increased numbers of medical students in 1918 the apprehension that in something like five years there would be no doctors is seen to be groundless. The proportion of women doctors, especially in the London area, is marked, and it is also common knowledge that a larger number of medical students than usual have commenced their professional studies before the age of eighteen. The grand total of students in May, 1918, is 7,630, of whom 2,250 are women, and that total compares favorably with the figures issued previously by the General Medical Council, as the grand total for May, 1916, was 6,103, while it was not until October, 1917, that the total reached 7,000.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

Y. M. C. A. HOTELS IN FRANCE—STATISTICAL REPORT OF RED CROSS WORK—BASE HOSPITAL NO. 3 (MOUNT SINAI UNIT) IN THE CHARTREUSE MONASTERY.

PARIS, July 9, 1918.

THE Y. M. C. A. is now operating fourteen hotels in France for American soldiers, with aggregate accommodations for 2700 men daily. Four of the hotels are located in Paris, five in port cities and the others in various large centers where American troops are stationed. In addition to the fourteen hotels, nine restaurants, not counting the canteens which serve lunches, are maintained by the "Y." The fourteenth hotel taken over is in one of the large ports of entry, and is one of the best hotels of that city. It has eighty-three rooms, equipped with all conveniences. During the month of April the hotels averaged 6,100 meals served each day, and the restaurants averaged 5,400 meals daily. The average cost of meals in the "Y" hotels is 4fr. 25c. The hotels and restaurants are run on a "break-even" basis. Mr. Walter C. Lohman of Dayton, Ohio, is in charge of the hotel and restaurant department.

In conjunction with these the Amusement Department of the Y. M. C. A. arranges a program for every night in the Paris hotels in a room set apart for the purpose, and such artists as Sothern, Elsie Janis, Mary Garden and others give their services free. The provincial hotels have programs of equal interest at less frequent intervals, the intention being to offer the men such attractions as will keep them occupied and away from less desirable places.

The report for April of the Military Affairs Department of the American Red Cross gives bewildering statistics regarding the work accomplished. The following activities are only a few that have increased to tremendous proportions: Seven canteens on the French lines of communication supplied 408,000 meals, nine metropolitan canteens supplied food and hot drinks to 454,000 and in addition to this took care daily of thousands of refugees, the number of whom was not kept. In the medical and surgical section a complete new hospital of 200 beds has been established in a chateau immediately behind the lines where fighting has been going on. A complete equipment for a thousand fracture bed tent hospital, including surgical dressings, instruments, etc., was installed. A dispensary was established for walking wounded and refugees. A complete tent infirmary was sent to an American division in the line.

American nurses and aids were placed in all the French hospitals where there are and will be American wounded. A hospital of 500 beds has been opened on the grounds of a famous racecourse with all necessary equipment and accommodations for operating. Three additional dispensaries and infirmaries for the American Army and Navy were opened at ports. Five rolling dispensaries were organized, with portable equipment, to care for refugees and soldiers by the roadside.

The report notes the great increase in the number of beds in numerous hospitals and the enlargement of all kinds of emergency hospital work, and the arrangements made for establishing new departments, such as dental and medical offices for the Red Cross personnel and the opening of various convalescent homes for American officers and soldiers. A unique feature which is proving a great benefit is the dental ambulance furnished to the Army by the Red Cross. It is mounted on an automobile chassis which moves from camp to camp behind the front lines, and 456 patients were treated in April.

Further details show that the Army has been supplied with 17,050 splints, 128,500 sponges, 25,255 slings, 122,200 bandages, 643,800 pads, 55,900 strips, buckles, hammocks, etc. Then 1,419 French hospitals were supplied with 5,343 cases, weighing 249,356 pounds, some of the articles being as follows: 2,500 surgical instruments, 1,000 mattresses, 4,500 pillows, 6,800 pillow cases, 1,500 pairs of slippers, 1,278 bedside tables, 5,492 sheets, 1,200 sweaters, 2,064 gowns, 325 beds, 1,200 shirts, 10,538 suits of underwear, 14,700 pairs of socks, 20,448

handkerchiefs, 13,700 towels, 1,456 blankets, 2,569 toothbrushes, and a great variety of surgical specialties and drugs.

A. E. F. hospitals were supplied with the following articles: 2,580 blankets, 4,943 pairs of socks, 10,500 comfort kits, 1,700 sweaters, 3,200 night shirts, 1,918 pairs of drawers, 350 pairs of shoes, 350 pairs of trousers, 500 first-aid kits, 2,800 pillow-cases, 4,648 sheets, 2,016 convalescent gowns, 1,080 face towels, 1,236 bath towels, 4,260 operating towels, 1,036 pairs pajamas, 2,160 napkins, 1,008 helmets, 30,786 handkerchiefs, 135 boxes of apples, and, in addition, hospital supplies of many kinds.

Every mondaine has heard and probably tasted of the world-celebrated liqueur "Chartreuse," made by an order of monks. These monks were expelled from France at the time of the contest between Church and State in 1903, and their ancient property dating from the middle ages was escheated to the State and has been lying idle all of these years. But suddenly it has been transformed, for the old cloisters resound to-day with the United States Army bugle call of Army Base Hospital No. 3—the old monastery has come to new life and usefulness. Gone are the pious Fathers from their cloisters. Instead, in their Sam Browne belts and C. D. uniforms, pace some of New York's leading surgeons and physicians. Base Hospital No. 3 (the Mount Sinai Hospital Unit), which left New York in the early part of February, 26 officers, 65 nurses, 5 female civilians and 153 enlisted men, took up its station in this fourteenth-century monastery, and after considerable preparatory work, received its first patients in May. The French Government had been preparing the buildings for institutional purposes, and the work was almost completed upon the arrival of the American hospital organization. The hospital unit found its station by the side of a winding little river, bordered on either side by tall Lombardy poplars. Just before the monastery is a grove of heavy balsams, and behind rises a gentle hill with a small village on its summit. The gardens of the old place have been replanted with flower beds by the Americans, and the old furrows have been sown with peas and potatoes. The grounds contain a variety of fruit trees.

The plan consists of the old main monastery building, seven of the monks' houses, and a number of new constructions which have been laid out following in a general way the design of a great cloister. The main building, the chapel of which was once famous for its carved woodwork, is used for the administrative offices (headquarters, registrar's office, etc.), the living quarters of the officers, the dispensary, the medical store-room, the laboratory, the recreation room for convalescent patients and enlisted men, the *x*-ray outfit, which is in one of the old chapels, and mess rooms for the officers and for the nurses. The great chapel is used as a large dining-hall (capacity 450) for patients and enlisted personnel; the chapel, though bare of its famous wood paneling, still retains its old stained-glass windows, and at the supper mess the sunlight of early evening is reflected in purple and orange through the western window.

The pharmacy of the monastery has been transformed into the hospital dispensary. The room still bears the inscription over the shelves "Salus Infirmorum, Ora Pro Nobis." When the Americans arrived they found the cabinets filled with the herbs, roots and dried leaves and flowers used by the monks in preparing their old-fashioned remedies.

The monks' houses, of which there are seven, will probably be reserved as officers' wards. Each house consists of three rooms on the ground floor and a garret, and has its own garden with trailing vines, an old well, and a niche in the wall where in other days stood some holy figure. The roses are in bloom to-day in these old gardens, and in one or two a touch of heliotrope wistaria creeps along the brick cemented walls.

The ward buildings, thirteen in number, are long one and two-story structures, modern, electrically lighted, provided with steam-heating radiators, running water, toilets, and covered walks for the convalescents. The capacities of the buildings differ, the largest being about 115 beds. The buildings are of cement, the rooms cheerfully lighted and the walls all newly whitewashed. They were built by the French, and admirably serve the American hospital demands.

The center of the great cloister garden contains three modern buildings, the central kitchen for the wards and two operating pavilions equipped with the surgical supplies and sterilizers brought from America and provided by the trustees of Mount Sinai Hospital and by the funds of the American Red Cross. In addition to the operating rooms there are separate rooms devoted to the work of the eye surgeon, the nose and throat specialist, the dental and jaw surgeons, the ante-operative *x*-ray examination, and dressing rooms for nurses and surgeons.

In the front grounds are the nurses' home, which is a four-story building, a small building for the chief nurse, another of similar construction for nurses' recreation purposes, and a building at present used by the nurses, but which will probably be used by the administration when the plant is enlarged. The old ox-stall barn has been converted into a garage. An open field immediately adjoining the plant offers opportunity for hospital expansion by the construction of the standard hospital barrack. The Engineer Corps is building at this time two bath barracks, one of which contains the bed and clothes disinfector.

Water for general washing purposes is pumped from the river. Drinking water is derived from five springs on the hillside behind the buildings, and is supplied to the plant by its own gravitation from its high source, about 80 feet above the level of the monastery.

146 Avenue des Champs Elysées.

Beriberi in Spain.—Fernandez Martinez states that beyond doubt beriberi has appeared on the coast of the province of Granada. The case which established this fact occurred in a native man aged 52 who led the life of a fisherman, day laborer, and shepherd. The climate is a torrid one, where cotton and sugar cane are grown, while away from the coast on the hills nearby, the weather may be extremely cold. The subject had always been well and free from vices. The diet comprised fried fish, potatoes, rice, tomatoes, oil, red peppers, chickpeas, and maize.—*El Siglo Médico.*

3. Acute Coryza. Its Intranasal Complications, Diagnosis and Therapeutics.—Ernst Danziger draws attention to the grave consequences that may result from a cold in the head. Acute coryza he describes as an acute infectious disease caused by the pneumococcus, streptococcus or bacillus influenza which are found chiefly associated with staphylococci. It is ushered in by a feeling of chilliness, with burning and itching in the nose, which leads to repeated attacks of sneezing, and in about twelve hours there is a colorless, seromucous secretion which, within a few days, changes to a thick, yellowish, greenish mucopus. The condition improves slowly and complete recovery usually follows in two or three weeks. The pathological processes which take place are: at the onset the mucosa is hyperemic, with a bluish red, glassy, dried appearance; as soon as the second stage of secretion is reached, the mucous membrane becomes swollen and edematous, and covered with watery secretion. It is the edematous swelling of the mucosa of the turbinated bones which prevents nasal breathing. The lower nasal meatus is also found filled with grayish, glairy mucous, which interferes with expiration. The usual treatment by administration of urotropin, aspirin, phenacetin, and so on, should be supplemented by local treatment in order to remove secretion, reduce edematous tumefaction, and establish good drainage from the accessory sinuses. The patient should irrigate the nose with warm saline solution (say one teaspoonful to a pint) a few times a day with the following precautions: the point of the nose piece of the syringe must not occlude the nostril; the stream must be horizontal; if irrigated from a douche bag, same must not be elevated higher than the ear; patient should bend the head forward during the irrigation; under no condition should the patient blow the nose directly after irrigation, and when he does blow his nose he must not touch either nostril. Danziger points out that it is not the irrigation, but the improper blowing of the nose afterward, that causes ear complications. After removal of the secretion, this author recommends an adrenaline ointment which reduces the swelling of the mucosa, and during the second week he adds a spray with an oil containing one of the volatile antiseptics. Should the nasal symptoms continue longer than three weeks, various etiological points have to be considered. (1) The presence of enlarged or diseased adenoid tissue in the vault of the pharynx, which must be looked for in adults as well as children. As a digital examination is contraindicated, and inspection with a retronasal mirror not satisfactory, the use of Holmes's pharyngoscope is to be recommended. (2) The possibility of an involvement of the accessory sinuses, which is usually caused by interference with normal drainage; this is more likely to occur in patients who suffer from anatomical abnormalities. Treatment should be instituted to establish normal drainage. Intranasal symptoms in these cases are of the greatest variety and intensity, and are sometimes entirely absent. In acute cases there may be intense pain over the antrum or frontal region, which with its periodicity might lead to a mistaken diagnosis of malaria. The cheek with the infraorbital or supraorbital region may be edematous, or the region of the antrum or frontal sinus only painful on pressure. As a rule, such cases yield to the conservative forms of treatment—as the application of adrenaline or cocaine to the region of the infundibulum, and irrigation with warm saline solution. In ease of swelling or severe pain, the ice bag should be employed. Sulphate of quinine, five grains three times a day, may be given. Other cases occur, however, in which prolonged nasal discharge or frequent headache is the only symptom present. Here resort must be had to other diagnostic methods, diagnostic puncture and lavage being the most reliable. In some cases a diagnosis may be safely made by transillumination, if intense transillumination on one side is obtained with a decided shadow on the other; it must be remembered, however, that a decreased transmission of light on both sides may be due to a thickness of bone that is normal for the individual in question. The third method of diagnosis, Roentgen pictures, Danziger has found unreliable and disappointing. Discussing the treatment of acute cases of coryza, Danziger states that if no relief is obtained in a few days by the conservative treatment already referred to, he uses puncture followed by lavage every twenty-four hours, three or four times, which seems sufficient to produce a cure. He points out that in these obstinate cases the secretion in the sinus is sometimes so thick that it cannot drain through the natural opening. During irrigation of the antrum the pressure of the water will often force a big plug of mucopus through the ostium and empty the sinus completely. Coffin and Harmon Smith have tried to supplant the puncture and lavage by suction and injection of antiseptics or astringent remedies into the sinuses after production of a vacuum. Danziger states that results are sometimes thus obtained which are due to passive hyperemia, but points out that prolonged hyperemia produces a swelling which might obstruct the ostia and prevent drainage. He also shows that it is immaterial whether saline solution or stronger antiseptics are used in irrigation, as the purpose is the removal of the secretion, the germs being embedded in the mucous or located deep in the glandular tissues of the mucous membrane. Should an enlarged anterior end of the middle turbinated bone prevent drainage, the removal of this obstruction is indicated. He adds that immunization with vaccines as a mode of prevention has been a complete failure in his hands, the reason being, in his opinion, that the normal bacterial flora does not represent the pathogenic germs.

5. The Too Intensive Arsphenamine Treatment of Syphilis.—M. L. Heidingsfeld advocates strongly the conservative method of arsphenamine therapy in syphilis and draws attention to the possible deleterious effects of too intensive treatment by this drug. He bases his conclusions on the careful clinical and serological examination of 1,133 cases of syphilis, treated in private practice from 1911 to 1918, and states that in this series 10,589 serological examinations have been made. Of the total number of 1,133 cases, 667 have been eliminated as unfit for careful report. The remaining 456 cases were under observation sufficiently long to permit of deductions, and of these 367, or 80 per cent., were clinically and serologically negative for two or more years, this negative phase being reached by 154 cases with only one administration of arsphenamine or neoarsphenamine, and in 107 cases with only two administrations. The other 65 cases were negative to the

Wassermann test and clinically negative but more or less persistently positive to the Hecht-Gradwohl control test. If these latter cases are added to the 367 cases, it means that of the series under consideration 95 per cent. proceeded to a clinical recovery. The mode of procedure adopted by Heidingsfeld was as follows: Every case of syphilis, not previously treated with arsphenamine, received a full commensurate dosage of arsphenamine, which was not repeated for four to six months, except in the face of a threatening and serious clinical manifestation. A serological examination was made every thirty days for the first six months. If there was no material change for the better, or the serological examination showed a relapsing character, treatment was repeated at the end of the first four months. If the serological examination showed improvement but was not negative, or if there were fairly well defined clinical manifestations, treatment was invariably repeated in six months. This plan was continued until the patient became persistently serologically negative and devoid of all manifestations of well-defined clinical nature. The serological control exercise consisted of the Wassermann test used in conjunction with the Hecht-Weinberg test, as modified by Gradwohl. Heidingsfeld expresses himself as supremely impressed with the combined efficacy, delicacy, and reliability of these tests in exercising the highest degree of diagnostic and therapeutic control. The author refers to the work of Ehrlich and Hata, who in 1910 produced "arsenic-fast" spirochetes, and to the later laboratory investigations of Akatsu and Noguchi, which have clearly established gradually acquired arsphenamine tolerance on the part of the *Spirochaeta pallida*. These observations would seem to confirm the results obtained in the present series. He refers also to the history of syphilis therapy and shows that before the cause of the disease was discovered the intensive and the conservative forms of treatment each had their advocates. From careful clinical observation, it had been noted that good results were obtained if antispecific remedies were entirely removed for a period of several months and temporarily replaced by a general tonic treatment, which in the light of our present knowledge can be explained by the fact that syphilis in a relatively short time acquires a tolerance to antispecific remedies, which is not removed until the individual is given a definite respite from further specific treatment. This may explain the supposititious value of remedies of the sarsaparilla type. The ideal goal in syphilis therapeusis would be reached if Ehrlich's concept of a "therapia sterilisans magna" could be attained. The arsphenamine remedies possess the maximum of parasitotropic and the minimum of organotropic activity of any that we have to-day, and it is possible that careful study of method and dosage may lead to improved results. It is noteworthy that the greatest degree of improvement, clinical and serological, follows the first administration, and it is possible that two or three quickly repeated treatments before arsphenamine tolerance has been established might give equally good or better results. Heidingsfeld decries particularly the long continued administration of small fractional doses, a form of treatment especially prone to establish arsphenamine tolerance. On the other hand, he is also strongly opposed to a too intensive therapy. This paper was read before the Section on Dermatology at the sixty-ninth session of the American Medical Association in June last, and provoked a good deal of criticism. Replying to the members who had taken part in the discussion, Heidingsfeld stated that his cases had been tabulated with the greatest care and he felt that his results could speak for themselves. In his opinion private cases were the only ones dependable for purposes of investigation. In dispensary and hospital practice he had had relapses, but the fault, he thought, lay with the individual and his mode of life. Speaking of dosage, arsphenamine should be administered in full dosage, 6 decigrams, commensurate to 160 or 180 pounds, body weight.

2. War Deafness, with Special Reference to the Value of Vestibular Tests.—P. McBride and A. Logan Turner point out the hypothesis that if there is deafness following concussion, and if the vestibular tests give a normal result, the prognosis is favorable and the deafness of purely functional origin is untenable and, if accepted by the examiner, might result in very grave injustice to the patient. While the authors have not been able to prove in any of the cases considered either functional deafness or malingering, they have been able to show that in Group A, where one or other of these conditions might be suspected, vestibular reaction was sometimes good and sometimes defective. In Group B they point out that in the only case of partial recovery after concussion deafness met with, it was the ear in which vestibular reaction was absent which recovered. Other cases in the series furnish ample evidence that vestibular reaction may be lost, while the cochlear functions are more or less active. In Group C they found unilateral deafness, the hearing in the other ear being good or fair. In only one case was vestibular reaction more marked in the better ear; in two this was reversed and in the other three cases it was equal. In one of the latter no reaction was obtainable from either ear, and yet the hearing power on one side was good. They conclude, therefore, (1) that concussion deafness is generally due to some organic change; (2) that the prognosis is usually bad; (3) that the results of the vestibular tests can only be utilized in conjunction with information derived from other sources. Thus, if the patient shows other hysterical symptoms, vestibular tests may perhaps under certain circumstances help diagnosis; but to state that they do more than this, in the opinion of these authors, is misleading and dangerous.

3. Nasopharyngeal Conditions in Meningococcus Carriers.—Captain F. J. Cleminson concludes from an investigation into the anatomical and pathological conditions of the nose and nasopharynx in meningococcus carriers that the following factors may suggest an explanation of the wide variation in resistance to treatment noticeable in such cases. He sums up his results as follows: (1) Factors favoring the genesis of carriers—(a) the presence of adenoids; (b) the conditions implied in the term "firm mucous contact." (2) Factors unfavorable to the genesis of carriers—already existing septic infection of the sinuses. (3) Factors favoring resistance to treatment—(a) pyorrhea alveolaris; (b) firm mucous contact; (c) already existing septic infection of the sinuses. Cleminson states, however, that these conclusions are based on so short a series of cases—47 carriers and an equal number of controls—that they must be accepted with the greatest

reserve; they offer the strongest inducement for a similar investigation on, say, three to five hundred carriers. In general it may be said that they point in the direction of the accessory sinuses as being the main seat of meningococcus infection in carriers, these cavities being often difficult to disinfect, and therefore able continually to reinfect the upper and more secluded portions of the nasopharynx, even though these may be swept clean periodically by the antiseptic used. Moreover, the lymphatics surrounding the olfactory nerves, which are in close relation to the ethmoidal cells, may possibly provide an easy avenue for infection of the meninges. It was thought that such an investigation as that undertaken by Captain Cleminson might result in some modification of treatment which would diminish the number of carriers and thus aid in maintaining field strength and also lessen the risk of outbreak. The author points out that such a result has already been attained, the above observations having led Captain Glover to precede flavine or other spray treatment at a fixed time by a spray of adrenalin chloride, 1 in 6,000, in normal saline. The effect of this reagent is, by shrinking up the mucosa, to increase the airway, dilate the ostia of the accessory sinuses, and allow of a much freer access of the antiseptic spray to all parts of the nose. This has been followed by a material improvement in results and has proved to be the best method tried in the laboratory this year. The author hopes to continue his research along lines indicated and suggested by the results reported. He believes that eventually it may be possible, as in diphtheria, to clear up an obstinate carrier of the meningococcus by some simple surgical procedure, such as the removal of the anterior half of the middle turbinals, by throwing open the ostia of the majority of the accessory sinuses, and thus shorten the period of isolation.

The Symptomatology of Osteomalacia from the Viewpoint of Polyglandular Endocrine Insufficiency.—Naegli enumerates the following symptoms: Osseous gracility, hyperplasia of the bone marrow, decalcification, sensitiveness of the periosteum which is markedly influenced by the exhibition of adrenalin; muscular dystrophies; psychic disturbances; increased reflexes, spasms, tremor, pyrexia, hyperhydrosis, paresthesia, disturbances of metabolism and changes in the hematopoiesis. As to lesions of the endocrine organs, insufficiency of the hypophysis and suprarenal gland has been met with, which is made evident by the happy effect resulting from the exhibition of the extracts of these glands. The hyperfunction of the genital glands is demonstrated by the influence of castration. The parathyroids are often hypertrophied; however, this phenomenon is common in all kinds of calciprivae diseases. After discussing the pathogenetic explanations which have been put forward for osteomalacia, Naegli concludes that the process can only be due to an endocrine affection, namely, a polyglandular insufficiency.

The Serology of Typhus Fever.—H. Werner and E. Leoneanu have been able to show that there is a positive Widal in 40 per cent. of patients with typhus, attaining even 1/400 in unvaccinated subjects. The sera of both typhoid and typhus agglutinate the Proteus X 19 or Eberth's bacillus. This agglutination is, however, more marked in typhus fever. In order to study the possibility of a serodiagnosis after the technique of Weil-Felix with the dead proteus, Werner and Leoneanu have, it seems, established the fact that the proteus heated at 80° C. for one hour becomes still agglutinated by the blood of typhus patients, but the reaction is less sensitive than in the case of the living proteus. The essays of the writers, as far as vaccination is concerned, are, to say the least, modest. One guinea-pig immunized to the proteus X 19 could not be made to take positive inoculation, while a healthy animal fell to the disease after an inoculation of typhus.

Changes Arising in the Cutaneous Capillaries in the Exanthemata.—Weiss and Hausland have been able to continue their researches on living subjects in the way of microscopy. They have been able—at all events, they say so—to study no matter what part of the cutaneous surface, by the following technique. A microscopic tube is mounted on a kind of a box containing a lamp and opened on its bottom. By applying the apparatus over the skin, which is imbibed with cedar oil, the vascular system is made to stand out, magnified to the extent of from 30 to 40 diameters. The writers offer a graphic reproduction of the images of a normal skin as well as the roseola of typhus and typhoid and the erythemata of scarlet fever and measles. The variations in aspect are in accord with the histological differences of these various eruptions and may have, perchance, a diagnostic value in doubtful cases.

The Antagonism of Chlorosis and Osteomalacia Considered Respectively as Disturbances of Hypo- and Hypergenitalism.—Naegli, with all the valor of a Teuton when a question of the genital organs comes in play, is desirous to establish, in the case of these two morbid processes, an opposition similar to that of myxoedema and Basedow's disease. To attain this important end he commences by reducing the domain of both affections, believing that very frequently an abuse is made of the diagnosis. Antagonism makes itself manifest, other than by the activity of the sexual glands, particularly in the domain of the endocrine, osseous, muscular, nervous and vascular systems.

Is Homo-Specific Blood Transfusion Dangerous?—R. Klinger criticizes the difficulties which Kuczinski (*Münchener med. Woch.*, April 30, 1918) maintains exist in the case of direct blood transfusion from man to man. The possible presence of hemolysins is not at all proven by Kuczinski's case because death may have quite as well been due to a septic process of some sort. Klinger concludes that, far from having a limited use, or being dangerous, transfusion should be much more extensively used than it is at present.

The Radiology of Gastric and Duodenal Ulcers.—G. Schwarz is opposed to the spasmogenous theory of ulcer. Likewise he does not believe in the neuropathic (vagotonic) theory of the cause of ulcer, but on the contrary he invokes this nervous state for the purpose of explaining the duration and activity of a preëxisting ulcer. The ulcer itself owes its genesis to mechanical or chemical conditions. An important part in determining the site of the ulcer is played by constriction of the abdomen at the waist line. It is for this reason that transversally placed stomachs, high in location, are more exposed to duodenal ulcer, while vertical stomachs develop ulcer of the lesser curve. The writer illustrates with diagrammatic drawings, taken from radiographs, the mechanism of these localizations which are made evident by shadows in the gastroduodenal area, these indicating the constant traumatism existing over the abdomen at the waist line. As arguments for upholding these views, the writer refers to the greater frequency of ulcer in women, as well as the increase in the number of cases since the beginning of the war. This increase is due, according to Schwarz, to the ever-increasing wasting of the poorer classes, a phenomenon which favors the action of abdominal constriction on the viscera.

Anemia of the Lower Limb Obtained by Compression with a Pad Attached to a Lever.—P. Drenitz does not think that Esmarch's band exercises sufficient compression in operations high up on the thigh; also that it slips down along the limb and does not allow one to make intermittent decompression during an operation. The writer uses instead a pad, which can be pressed upon the femoral or iliac artery or even the aorta, by means of a lever. Manual pressure is employed and can be graded to suit the circumstances. The apparatus is very clumsy.

Analogies of Rabies and Tetanus.—Remlinger shows that in experimental pathology these two infections behave almost like members of one group.—*Société de Biologie.*

Book Reviews.

Minor Maladies and their Treatment. By Leonard Williams, M.D., Physician to the French Hospital. Fourth Edition. Price, $2.75. New York: William Wood & Company, 1918.

The reader of this very useful and readable book should begin with the preface. In so doing he will make the acquaintance of a very engaging personality—on paper, and we doubt not he is such in the flesh as well—and will be prepared to take the advice given in the book as based upon the experience of a (presumably) successful practitioner who has an open mind and implies that what he has to say is not necessarily the last word in therapeutics. The minor maladies, whose treatment is discussed, are: "Colds, coughs, and sore throats;" "Indigestion;" "Constipation, diarrhea, vomiting, and giddiness," a chapter which contains some practical remarks on seasickness; "Rheumatism, neuralgia, headache;" "Goutiness;" and "Minor glandular insufficiencies." There are also suggestive chapters on "General health," "Old age," "Some drugs and their uses," and "Insanity."

The book can be profitably and agreeably read through, and then left on the shelf as a work of reference, and it will prove to be one of greater practical utility than many another much more ponderous tome—the ponderosity of this is just about one pound. We can recommend the book to all who believe in the value of treatment, even of the minor maladies, which of course make up the bulk and the most lucrative part of the general practitioner's daily work.

The Way Out of War. Notes on the Biology of the Subject. By Robert T. Morris, F.A.C.S., Author of Tomorrow's Topics Series. Price, $1. Garden City and New York: Doubleday, Page & Co., 1918.

This little book constitutes the fourth volume of the Tomorrow's Topics Series, the previous volumes being "Microbes and Men," "A Surgeon's Philosophy," and "Doctors versus Folks." To any one who has read these books, especially the first named, the announcement of another one, dealing in Dr. Morris' interesting fashion with the great war as well as with warfare in general, will be most welcome. The author notes the various attempts to explain the fact of war which have been made by sociologists and psychologists and says they have been without practical results because they have approached the subject from the wrong side. His own explanation is a materialistic one, based upon biology. War is due, in fact, to man's defective brain. This, of course, is not the whole argument, but we will leave to the reader the pleasure of learning for himself Dr. Morris' view of what led the German to adopt the infamous practices which have made this name a synonym for all that is base and ignoble.

Laboratory Methods of the United States Army. Medical War Manual. No. 6. Compiled by the Division of Infectious Diseases and Laboratories, office of the Surgeon-General, War Department, Washington, D. C. Price, $1.50. Philadelphia and New York: Lea & Febiger, 1918.

The volume deals with laboratory technique—stains, solvents, reagents, culture media, etc.—with special reference to the examination of urine, blood, sputum, feces, milk, drinking water. Elaborate details are given for serореactions of all kinds, quantitative analyses of urine and the preparation of smears and cultures. The following substances are mentioned in blood analyses — glucose, chlorides, hemoglobin, urea and non-protein nitrogen. No manual is given for creatinine, uric acid and indican.

Aids to Rational Therapeutics, with U. S. A. Pharmacopœia Equivalents. By Ralph Winnington Leftwich, M.D., C.M., M.R.C.S. Eng., Late Assistant Physician to the East London Children's Hospital; Author of "An Index of Symptoms," "Tabular Diagnosis," "A Pocket-Book of Treatment," etc. Price, $1.50. New York: William Wood and Company, 1918.

This is a very practical little book on the treatment of disease that cannot but be found useful to every practitioner, young or old; the only one to whom it will not appeal is the dyed in the wool therapeutic nihilist, whose sole object in studying disease is to find out the how and the why, and who would hate to think he could cure it for that would put an end to his investigation and spoil all his fun.

The author has adopted a plan of classification of diseases which is admirably suited to the purpose of his book. He abandons the old plan of grouping them according to the organ affected, in which diseases of the most varied character and entirely unrelated to each other are considered together. This involves a great amount of useless repetition, since the underlying principles of the treatment of catarrhal inflammation—to take an example—are the same, although modified more or less according to the organ affected. Dr. Leftwich holds, however, that the only scientific way of teaching therapeutics is to place in the same group all diseases which are of the same or allied pathology, whatever organ or tissue may be involved, while the shortest practical way is to place in the same group diseases which require the same treatment. As one may readily see, these two groups more or less coincide. On this double basis diseases are divided into forty groups, such as the catarrhal group, the serous effusion group, the purulent flow group, the rheumatic group, the chronic fibrosis group. The group treatment is first considered and then the treatment of each individual member of the group so far as it may differ from that of the type or of other members. This makes a very practical book, one that is adapted for study as well as for reference.

Lessons from the Enemy. Medical War Manual. No. 5. By John R. McGill, M.D., F.A.C.S. Major, Medical Reserve Corps., U. S. Army. Price, $1. Philadelphia and New York: Lea & Febiger, 1918.

The chapters are devoted respectively to the German Medico-Military Organization, Sanitary Service, Base Hospitals, Red Cross Activities, Reeducation of the Disabled, Orthopedic Hospital-School and Workshops, Protheses, National and Communal War Relief Work, Social Health Insurance, etc. There are many illustrations and specimen blanks to be filled out by the disabled.

Tumors of the Nervus Acusticus and the Syndrome of the Cerebellopontile Angle. By Harvey Cushing, M.D., Professor of Surgery at Harvard University, Surgeon-in-Chief to the Peter Bent Brigham Hospital, formerly Associate Professor of Surgery at the Johns Hopkins University, Director of the United States Army Base Hospital No. 5. Illustrated. Price, $5.00 net. Philadelphia: W. B. Saunders Co., 1917.

We are only lately beginning to realize how little we really know about such a body as the motor cortex, for example, in spite of our many opportunities to observe the physiology and pathology; and when it comes to localizing a brain tumor the average practitioner will give up at once and send for the neurologist. And yet brain tumors are fairly common and have well-defined symptoms. Neurofibromata, *e.g.* comprise about one-tenth of all of them, and their usual location is in the cerebellopontile angle, yet are the symptoms known generally? Dr. Cushing has given us here a careful study of 29 undoubted cases and many other probable ones, together with illuminating and in the main undeniable generalizations drawn from them. In places the book bears marks of hasty construction, which is explained—and honorably explained—when we know that Dr. Cushing was suddenly called "over there." This reminds us that the present war is responsible for the death of Sir Victor Horsley, to whom, more than to any other man, is due the credit for the modern knowledge of, and interest in, brain surgery. Dr. Cushing is carrying forward the torch he lately relinquished, and in his hands it promises to burn with a clear, steady flame.

Dr. Cushing's cases are reported clearly and fully, illustrations are profuse and, for the most part, helpful. The chapter on diagnosis is especially good. Paper, binding and print are excellent except that the case reports themselves are in rather too fine print and there is altogether too much spacing of letters and words to fill out lines. This gives a crude appearance to an otherwise finished example of the printer's art. Altogether the work is a classic and one to which any physician might point with pride on his shelves.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held April 22, 1918.

THE PRESIDENT, DR. HOWARD CANNING TAYLOR, IN THE CHAIR.

Resolutions Providing for Legislative Bureau at Albany.—Dr. GEORGE W. KOSMAK introduced resolutions which read in substance as follows: "Whereas, the present system employed by the Medical Society of the State and County of New York, and the constituent societies, for the purpose of studying and controlling or influencing medical legislation of direct interest and importance to the medical profession of the Commonwealth is impracticable, inefficient, and unproductive of results, and constant attempts by legislators and other interested lay persons to influence the practice of medicine, to invade the legal and other restrictions surrounding the same, to burden the legitimate practice of medicine with unjust and unfair laws and requirements, demand constant watching by a qualified and satisfactorily organized central officially recognized group, and as this condition of affairs demands speedy relief, be it *Resolved*—That the Medical Society of the County of New York instructs the establishment of a Legislative Bureau at Albany under appropriate rules and regulations formulated by the Counsel of the State Society, which shall centralize and co-ordinate the work of the State and local Committees on legislation, and furthermore, be it *Resolved*—That the Medical Society of the County of New York instructs the establishment of a standing Committee on Legislation of the Medical Society of the State of New York, consisting of three members, the chairman of which shall reside in Albany, and be it *Resolved*—That the necessary expenses incident to the work of such a committee be defrayed by the State Society, by certain economies secured in connection with the publication of the State Journal and by a direct assessment on the members of the State Society if necessary, and finally be it *Resolved*—That the delegates from the Medical Society of the County of New York to the Medical Society of the State of New York at its annual meeting be instructed to present these resolutions in the House of Delegates."

These resolutions were adopted subject to revision which would not change their purport.

The Whitney Drug Bill.—Mr. JAMES TAYLOR LEWIS, Counsel of the Medical Society of the State of New York, made a brief address in which he urged as many physicians as possible to go to Albany on the following Wednesday to attend the hearing on the Whitney drug bill and to protest against the passage of this measure, which he characterized as the most vicious piece of legislation that had been known in twenty years. He scored the doctors for having permitted the bill to pass the Assembly, and urged the physicians who went to Albany to advise the Governor not only to veto the bill but to denounce it. Mr. Lewis said he doubted very much whether most doctors fully understand the provisions of the Boylan bill or of the Whitney bill, and yet each doctor would be taxed one dollar a year for its support. The bill reduced the crime of illegally selling narcotic drugs from a felony to a misdemeanor, and for the first time in the history of medical legislation in this State a doctor could have his license taken away from him for a misdemeanor.

Fate of the Health Insurance Bill.—Dr. KOSMAK reported that at a hearing on the Nichol bill, which provided for a health insurance, the doctors had appeared in such force and with such effective arguments that the bill was killed in committee. While that disposed of the health insurance bill for this term of the Legislature, there was no doubt that another bill would be presented next year.

Resolutions for Increase of Public Health Committee.—Dr. J. P. DAVIN introduced the following resolutions which were adopted: "Whereas, a number of political measures and policies are publicly advocated at the present time as public health measures and as based on sound and established principles of medicine, when in reality they have no such sanction, but are merely the reflection of personal opinions of individuals in private practice or in public employ, and Whereas, the collective judgment, authority, and experience of a representative body of the medical profession, such as this Society, should be of inestimable service in determining the value of such procedures before they are legislated upon, be it therefore *Resolved*—That the Public Health Committee of the Medical Society of the County of New York be increased in numbers and importance so that it may correspond to the Public Health Committee of the New York Academy of Medicine, now actively engaged in work of this character. This committee should report monthly to this Society to the end that the public might be advised with authority on such subjects and that the rights and duties of practitioners of medicine and the welfare of the community shall be conserved in all matters of legislation advanced as public health measures." These resolutions were adopted.

Resolutions Opposing Health Insurance.—Dr. WILLIAM S. GOTTHEIL presented resolutions instructing the delegates from the Medical Society of the County of New York to the Medical Society of the State of New York to oppose health insurance, and instructing the delegates from this society and from other county medical societies to the American Medical Association to oppose health insurance.

The Problem of Venereal Disease Control.—Captain A. N. THOMSON, M. R. C., of the Surgeon General's Office, Washington, D. C., made this presentation, in which he said that the problem of venereal disease control in the army was to all intents and purposes the same as in civilian life. Those who had entered the Medical Reserve Corps were finding in their army experience confirmation of the basic principles that they had evolved in health department and clinic control of venereal disease during the past ten years. This, in brief, might be divided into education, first; advice and diagnosis, second; treatment, third, and last, but not least, follow-up, in every possible way. Military discipline greatly expedited the application of all procedures for control both of the source of the infection and the treatment of the infected individual.

Prior to entering the service, men who had given the venereal disease problem attention had the idea pretty firmly fixed in their minds that the army spread venereal disease. A good many people still held that idea, but contact with and study of the military procedure soon demonstrated that all civilian control methods were in force, and because of military procedure, which was another way of saying discipline, were more efficiently in force. The method of attack upon the venereal problem in the military as in the civilian plan started with education. By War Department regulation every man in the army must be instructed upon venereal disease. The education, therefore, was not only to be made available for the new army, but was in operation in the regular army. The recording of venereal disease in the army was most complete. Advice and diagnosis were available and treatment was compulsory, with penalties attached for failure to report. Follow-up work was also an actuality, and the medical officer finding that his patient did not come back had only to report the matter to the commanding officer in order to have the patient produced. Quarantine was also enforced. While in the infectious stages of the disease no man was given leave of absence from the reservation. The point which the speaker particularly desired to make was that the army was not to blame for venereal disease, and that we must all realize that the source of infection was in the civilian community, and the responsibility lay without the military reservation and not within. They were beginning to have some sort of an accurate index of the incidence of venereal disease in the community. The figures were now being reported in two groupings, all classified as new to the army, one group being contracted prior to enlistment and the other group contracted after enlistment. During two recent weeks, of 3,800 cases of venereal disease that were new to the army, 675 were contracted after enlistment, and if something were allowed for duplication, we would find that the civilian community presented the army in a period of two weeks with

3,000 venereal problems. If one realized the amount of work entailed in taking care of 3,000 patients, and at the same time attempting to make them into soldiers, it would be evident why every effort was being made to impress upon the civilian community the need for an active campaign against venereal disease, and why so much time and energy were being expended upon control measures within the army. The plan of the Surgeon General for combating venereal diseases was comprehensive, and comprised (a) social measures to diminish temptation, (b) education of soldiers and civilians in regard to venereal diseases, (c) early treatment and prophylactic measures against venereal diseases, and (d) medical care. The work of diminishing sexual temptation by the suppression of prostitution and the liquor traffic and the substitution of healthful and desirable recreation was being carried on under the general supervision of the Commission on Training Camp Activities, with its various cooperating organizations. The educational program for both soldiers and civilians covered lectures, pamphlets, exhibits and automatic lantern slide projection that would substitute for a lecturer and the use of the motion picture. The army could and did provide this material, and could and would make the audience attend. Bodies such as the New York County Medical Society should endeavor to reach the civilian population with the same degree of thoroughness that the army was now using. The motion picture exhibition would explain what they were doing in the army and what could be done in the civilian population better than mere words. Dr. Thomson said that the one thought he wished to emphasize was that man power would win this war. The experience with the original draft must bring the realization of the large incidence of venereal disease in the civilian population, the man power of which would become our army. It must be further realized that we would need millions more men. It therefore became the patriotic duty of the civilian communities, as well as to their own great advantage, to present to the army men free from venereal disease. To do this, all known scientific procedures must be instituted. In closing, Dr. Thomson urged the Society to enlist in the warfare against venereal disease, so that the country might be presented with an army fit to fight and industrial forces fit to work.

The Value of the Nervous and Mental Examination in the Army.—Dr. JOHN J. MCPHEE presented this communication, by invitation, in which he said that the shock and strain and savagery men experience in this war had made neurologists and psychiatrists indispensable to its medical service. A normal nervous system was necessary to withstand its terrors as a healthy body to bear its exposure, exertion, and fatigue. Our medical officers, internists, and surgeons, in our Clearance Hospitals, had written about the number of "nervous wrecks" they were getting, especially from the forces we sent over at first and complained about the lack of practical and experienced men to look after them. They had told us that these men should not have been allowed to go over at all. They were occupying beds that were needed for more dangerous but recoverable conditions, and time that could be saved if they had competent advisers was lost while the Disability Board was considering what to do with them. It was obvious that time could be saved and efficiency favored by having expert opinion available when required. If these needs could be met, and at least one mature man put on the staff of each division surgeon in the field, we would have done our duty to our men overseas. But this was not enough. They had written us not to allow unfit men to go over, and to attain this end we must reject them on our draft boards and in recruiting stations, or find them in our camps and recommend their discharge. Dr. McPhee stated that though his work in camps and on draft boards was limited, it had been sufficient to teach him its value and its wants. Men might get by local examiners, however careful they might be, without showing certain defects, and then reveal them under the discipline and strain of camp life. And no doubt many that would stand camp life and seemed fit soldiers might not hold out at the front. We could stop most of them at the source and comb more of them out of our camps if we could get enough time and men to do it. The speaker related his experience in examining some 40,000 men in our armies and suburban camps, many of them being National Guardsmen as well as men belonging to the National Army. He found that among them mental defectives were common and came from all parts of the country, there being more of them from the larger centers of life and from communities whose proportion of illiterates was large. All of them had been failures at school and at any work that required understanding and training. Most of them were harmless but useless, because they could not understand discipline or carry out orders. It was a relief to the officers and men and a benefit to the Army to get them out of it. There were a large number of recent recruits who were nervous and anxious when they were examined. They had tachycardia and various tremors, and their responses were often misleading. Many of them were homesick and presented a group of signs that might suggest a serious underlying cause. Drunkards and drug addicts were few. Of nearly 2,000 registrants examined by the Advisory Board at the Post-Graduate Hospital, five, or less than one-half of one per cent., were drug addicts; three, or less than one-quarter of one per cent., were drunkards; 13 were mental defectives, and seven were epileptics. A surprising number of bed-wetters were found. They seemed normal in other respects and were useful soldiers. It was sometimes a bit puzzling to know what to do with them. Another unexpected finding was the number of men with goiter. There seemed to be some cause for it in certain districts of Ohio, as there was a large number of men with goiter in the Ohio Infantry, and regiments and battalions from adjoining states appeared to be affected by it. Men who had constitutional symptoms or gave a story of previous constitutional disturbance, or in whom the goiter was very large, were not held in the service. There were many other ills and defects of the mind and nervous system, but these groups referred to were sufficient to convey an idea of the value of special examiners to the Army. Malingerers and adherents of various cults, intellectuals, and other suspicious characters, came within the province of the neurologist and psychiatrist, all of whom were a menace to the discipline and morale of their companies. Their discovery, exposure, and discharge was one of the most welcome and profitable services that the medical officers could render. In closing, Dr. McPhee stated that among the men with whom he had come in contact there was no selfish interest or sectional feeling. They were superior men on the same level and impelled by the same spirit to give their all for their country and its cause. They were doing it now in the trenches, and deserved and must get the best care we could give them.

Major GRAEME M. HAMMOND, M.R.C., U. S. A., laid great stress on the plea made by Dr. McPhee for early, complete, and thorough mental and nervous examination of all troops going to the front. He stated that he had examined about 75,000 troops from various camps, many of them having been examined a second time after an interval of three months had elapsed since the first examination. His experience had included a large number of National Guardsmen as well as men in the National Army. The National Guardsmen were men of a high type, the kind of men that we wanted for service at the front. He had found that, on an average among all classes, about 3 per cent. were discharged for mental and nervous diseases. The lowest percentage was found among the soldiers of the Seventh Regiment and in Squadron A, New York State Guardsmen. From these two organizations less than 1 per cent. were rejected for mental and nervous diseases. The highest percentage of rejections was from a Southern State where 30 per cent. were illiterate and 3 per cent. were rejected for mental and nervous diseases. As Dr. McPhee had stated, in an Ohio regiment he had observed a great number of cases of hyperthyroidism, though there were few cases of the exophthalmic type, but there were many enlarged thyroids, sometimes with constitutional symptoms and sometimes without. In one Ohio regiment over 2 per cent. were found to have enlarged thyroids, and they had also found many instances of hyperthyroidism in an Iowa regiment. It was among

the Camp Upton men who were drafted largely from the East and West sides of New York City that the drug addicts were found. There were very few drug addicts among troops from other localities. They had found no drug addicts in the Rainbow Division. Among the Camp Upton recruits they had found some 200 heroin and other drug cases, and these men were discharged from the service. The drug addict was not fit for a line soldier, but might be useful for other work. A number of addicts had gone to Europe since, so long as they were able to get the drug they had escaped detection and were continuing to get their drugs on the other side. It was only when their money gave out and they were unable to obtain their drug that they showed the symptoms of deprivation and were then detected. Inquiry among these 200 addicts referred to showed that they began taking drugs between the age of sixteen and seventeen years, and it stood to reason that this was the age at which a large number of young people in New York began taking a drug. Almost invariably the drug was first given to them, and then they tried taking a few doses, and after that they took all they could get. As to the conscientious objectors, Major Hammond said he had seen about 80 of them. They were of three classes. The first class were those who were conscientiously opposed to fighting. This class formed not more than 1 per cent. of conscientious objectors. The second class was composed of those suffering from some psychosis. The third class, which embraced about 95 per cent. of the conscientious objectors were simply yellow all the way through and would not fight under any circumstances whatever. They would suffer ridicule, disgrace and any punishment short of death, rather than risk their lives in battle. The speaker illustrated these classes by citing specific examples. They had a large number of nervous and mental cases in the Camp Upton Base Hospital. There were two wards having accommodation for 40 patients, and they had some 75 patients in those wards. They did not make any attempt to treat these cases, because in a cantonment the mental and nervous department of a hospital was mainly for the purpose of ascertaining the actual condition of these men and holding them until they were discharged or sent to an institution or returned to duty. He had thought, when he went to Camp Merritt, that he would find very few mental and nervous cases, as most of the soldiers had been examined before at other cantonments, but to his surprise, he had found a good many cases of abnormal mental states, but very few cases of nervous disease. The class of cases most frequently met with were the mental defectives, morons, paranoids, dementia praecox cases, and epileptics. The Government was eliminating an enormous amount of nervous and mental material before sending the men over, and was not waiting until afterward when it would be too late.

Dr. Ellice M. Alger said he hesitated to discuss Dr. McPhee's paper because he was not a neurologist, while his work among recruits had been confined to an Advisory Board. There were, however, several points that occurred to him. The neurologic, and especially the mental examinations, were in some respects more important than the physical. The best soldier, like the star athlete, was the man who in a pinch always did a little better than he knew how, who was stimulated rather than depressed by crises, and this, of course, was particularly true of the officers. It was psychological and did not always go with bodily health. Many of the world's greatest achievements had been by men whose sheer determination to win rose superior to serious physical defects. Caesar and Napoleon would both have been ineligible for our army because of epilepsy, William of Orange and Guynemer because of respiratory defects. If Nelson had been retired when he lost his eye, he would never have fought Trafalgar, and the history of the world would have been entirely different. We had our own great public character whose will to fight no one questioned, but who was refused the opportunity because of an eye lost in battle. It would sober us to think that the destiny of the whole world might depend on some obscure physician finding a little albumen in some great man's urine or pronouncing him defective in vision. The speaker wondered what the world would have been if, in the less civilized parts of the earth, medical science had been far enough advanced to close the army to the man with the withered arm. The point he wished to make was: That, instead of spending all our energy and ingenuity in detecting the malingerers who were of no use after we drafted them, we might well spend a little loving care in helping these other malingerers who were wearying heaven and earth in their efforts to get to the front; to spend less time in seeking drug addicts and more on fight addicts. This, the speaker averred, was distinctly in the province of neurology, and few men were more capable of recognizing real militancy than Major Hammond and Dr. McPhee.

Dr. Percy W. Roberts emphasized the fact that almost all advisory boards were impressed with the importance of these mental and neurological examinations and to the necessity of having them well done. From the orthopedic standpoint the speaker saw three types of men referred to the advisory board. One expected to be taken and accepted the examination as a matter of course. The second class of men were those who were nervous for fear that some slight defect was going to debar them from service. The third class were those who exaggerated their defects so that they would be rejected. Among this latter class one found all sorts of orthopedic conditions simulated. For instance, there was one man who expected to get out of service because seven years ago he had a fracture of the patella, and he actually believed that that old fracture would be a cause for his rejection because of an assumed limp. Dr. Roberts cited a number of specific instances illustrating this latter type of men, and referred to a typical example occurring in a man who had a club foot which could easily have been corrected. This man had never done any work, and said he did not want his deformity corrected because then he would have to work. On the other hand there were the men who were overjoyed when they learned that a defect which they had feared would debar them could be corrected and that they would be accepted for service. In closing, Dr. Roberts emphasized the fact that it was the man with the will to fight who was wanted.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, April 24, 1918.

The President, Dr. Frank C. Hammond, in the Chair.

Recognition and Treatment of the Anemias.—Dr. Alfred Stengel said that, summing up all cases of anemia, there would be relatively few of the so-called primary anemias and a very great many of the form termed secondary anemia. The secondary anemias or the simple anemias, analyzed from the standpoint of cause, might be grouped under: (1) Infections; (2) Those following hemorrhage, manifest or concealed; (3) Those due to some form of intoxication. While lead was the recognized form of poisoning it was to be remembered that at the present time new poisons were being encountered, and that cases resembling those heretofore termed pernicious anemia might be due to T. N. T. poisoning. A 4th group represented the parasitic anemias; a 5th, the anemias expressive of some deep seated, perhaps overlooked, neoplasm. Infection was regarded as probably the cause of the very great majority of anemias seen in ordinary every day practice and these cases were mainly important where the infection was not manifest. It was often observed that young boys and girls who were anemic would improve under iron and arsenic, but afterward relapse. While the belief was held that they had a constitutional tendency to anemia, as a matter of fact there was failure to recognize the cause of the anemia. It was possible to recall cases of anemia in young women and boys with valvular lesions of the heart. The condition was one of chronic infection. They literally ate iron and were thus kept in a reasonably good condition of health. Such young people were also seen with large cystic infected tonsils constantly relapsing because the infection was allowed to remain.

The attitude of practitioners, Dr. Stengel felt, had been all wrong in such connection. In the post-hemorrhagic anemias there were said to be the open and the concealed hemorrhage; in the latter instance mistake in diagnosis was not unlikely to be made. The longer the duration of an anemia the more it approached in its clinical appearance a pernicious and an aplastic anemia. The bone marrow became tired out and the patient's appearance was that of pernicious anemia. In such a case, although the cause of the anemia might be removed, the patient did not get well, the anemia habit having become established. The blood regenerating function was absent, and while the blood did not show the characteristics of pernicious anemia the patient remained anemic during life. In the question of treatment Dr. Stengel was not so much concerned with the form of iron and arsenic used as in finding and removing the cause; surgically, if focal. Transfusion was indicated in acute anemia due to loss of blood. Splenectomy in his judgment was one of the most valuable adjuncts in the treatment of certain types of anemia that had been discovered. It was, however, a very serious procedure, and the case must be selected.

Value of Splenectomy in the Treatment of Some of the Anemias.—Dr. JOHN B. DEAVER said that the leading indication for splenectomy was probably traumatic injury. Inspection would soon indicate whether or not the organ should be removed. Injury to the hilus without doubt demanded removal; a slight wound of the cortex might be treated conservatively by some surgeons, but if there was any doubt, removal was the safer course. Neoplasms of the spleen were rare, but demanded splenectomy, unless there was evidence of metastasis. Wandering spleen was often associated with splenic enlargement. It might be treated by splenopexy or splenectomy according to the case. A more common condition of enlargement was that due to Banti's disease. While its etiology was not definitely known, it was known that removing the spleen had obtained a cure in a great many instances. While some recoveries had been reported from operation in the later stages of the disease, and personally Dr. Deaver had had the experience, such surgical treatment was attended with great risk; early operation had been attended with such good results that it should be resorted to without hesitancy. The mortality appeared to be about 11 per cent. We are told that the best results of splenectomy are obtained in the treatment of hemolytic jaundice. Eliot and Kavanel in 48 cases collected in 1915 report only 2 deaths, a mortality of 4.2 per cent. Krumbhaar in 1916 had collected 156 cases of pernicious anemia treated by splenectomy with 30 deaths. The Mayo Clinic reported 31 splenectomies for pernicious anemia up to April 1, 1916, with 3 deaths, or 9.7 per cent. mortality. Of the survivors, 22 or 78 per cent. showed continuous improvement; of 16 followed up for six months, 11 continued to improve and 3 had had relapses. From the experience of the Mayo Clinic it would appear that splenectomy for the relief of pernicious anemia should be considered in youthful and middle-aged subjects showing good general resistance and where splenic enlargement was moderate and there was evidence of hemolytic action. The degree of hemolytic activity was estimated by the blood pigments, urobilin, and urobiligen in the duodenal contents. A comparison of the degree of hemolysis with the severity of the anemia seemed to indicate the degree of productive power of the bone marrow. Hemoglobin below 35 per cent. or erythrocytes less than 1,500,000 increased the operative risk. An improvement in the blood picture and in the general condition might be obtained by preoperative blood transfusion. In a few instances blood transfusion for postoperative relapse had been successfully employed in the Mayo Clinic, but not adopted routinely. The treatment of pernicious anemia by splenectomy, Dr. Deaver said, was still on trial and apparently was merely palliative. There was, however, reasonable hope for improved results. In the aplastic type of the disease splenectomy was contraindicated. Splenectomy was also contraindicated in leucemia. His experience concerned a few cases of Banti's disease and of pernicious anemia. He knew of at least one operated case of Banti's disease in which the patient lived comfortably for several years, dying later of hematemesis. Dr. Deaver had operated late Banti's cases in the presence of ascites with good result. The few cases of pernicious anemia which he had operated had shown the same fluctuations of improvement and relapse which seemed to characterize the condition.

Dr. HARRY LOWENBURG called attention to a method of blood transfusion in infants not touched upon. Within the last month he had on three occasions effectually done a transfusion in the longitudinal sinus through the inferior fontanelle. The technique was simple and the result brilliant. One referred case was that of a child of 16 months of age with a hemoglobin of 30 per cent. and 1,560,000 white cells. Dr. Lowenburg had studied the case along the lines suggested by Dr. Stengel, knowing that every anemia had a cause. The baby had had bloody stools for about a year. It was impossible to determine whether this condition was responsible for the anemia or was caused by it. As a last resort he had tried transfusion by the method mentioned. The hemoglobin had been raised to 65 per cent. and the leucocyte count to 4,800,000. The child had had no bloody stools since the first transfusion. Attention was called to the procedure as a valuable but much neglected means of intravenous medication.

AMERICAN THERAPEUTIC SOCIETY.

Nineteenth Annual Meeting, Held at Richmond, Va., June 7 and 8, 1918.

DR. W. WAYNE BABCOCK OF PHILADELPHIA IN THE CHAIR.

(*Continued from page 305.*)

Surgery in Its Relation to the Psychoses and Psychoneuroses.—Dr. ROBERT T. MORRIS of New York read this paper. (See page 315)

Drug Addiction and Its Treatment.—Dr. JACOB DINER of New York read this paper. (See page 316.)

Dr. E. ZUEBLIN of Cincinnati said that he would congratulate Drs. Morris and Diner on their presentations. In dealing with psychoses and psychoneuroses, it was unfortunate that the psychologist seemed to have gone his own way in disregard of the practical experiences of his medical colleague. Notwithstanding the resistance of the medical practitioner to things pertaining to the so frequently misunderstood domain of psychoanalysis both parties meeting on common ground could learn from each other. Freud in his studies had gone far to shock both patients and physicians by his revelations which contained a grain of truth not to be disregarded entirely. All possibilities ought to be considered in these border line cases, whether the manifestations were due to a functional or organic disturbance of the nervous system. At the time of Hippocrates hypochrondria or melancholia was connected with intestinal or hepatic disorders; in our epoch, when we were better acquainted with the functional relation of the sympathetic nervous to the central nervous system, such a conception would meet less criticism. Dr. Diner had laid stress on reeducation, which, in the speaker's opinon, should not be restricted to the drug habit alone, but ought to be considered in most of the cases treated medically. In contracting disease the patient somehow had erred against the rules of proper hygiene, against proper nutrition, and in paying the penalty for his error with morbid symptoms the patient must learn how to avoid the recurrence of similar manifestations.

Dr. HENRY BEATES of Philadelphia said that the point was well taken that the asylums would have fewer inmates if attention were accorded to certain conditions, and among them hereditary unstable and hypersensitive nervous systems. So to train mentation that a well established equilibrium was formed between the intellectual, emotional, and volitional was the principle involved, and so training drug habitués through a specially developed pedagogic art was the task to be perfected. As to hereditary psychic hyperesthesia, infections and toxemias of chemical and biochemical origin played a potent role in provoking psychoses. Two sisters, whose grandfather was noted for furious temper and who died of cerebro softening, and whose father

was in earlier life an alcoholic, both developed a psychosis—one from decayed teeth and peridental abscess, the other from retained secundines after parturition. The surgical correction of the mouth and of the uterus respectively resulted in complete recovery after a few months. The dental case remained well for six years when abscess of a molar resulted in a return of the same condition. The patient at once consulted the speaker and in less than an hour the tooth was extracted. That very night, Dr. Beates said, the mind became normal.

Oral Infection in the Causation of Systemic Diseases and Their Bearing on Treatment.—Dr. HARRY BERTRAM ANDERSON of Toronto, Canada, read this paper. (See page 311.)

Dr. HENRY BEATES of Philadelphia said that the wife of a Philadelphia surgeon was supposed to have a cerebellar neoplasm. She had remarkably beautiful teeth. However, a skiagram was taken of the mouth and 7 apical abscesses were found. The teeth were removed and a few days later the symptoms entirely disappeared. It was not necessary always to advise extraction when the skiagram showed suppuration, but one should defer to the opinion of a competent, skillful dentist who could tell what could be done in the way of prophylaxis. Some cases of inflamed peridental membrane could be successfully treated. Another physician was told that he had a malignant growth at the angle of the jaw. The mouth was examined and a crown which had been on for ten years appeared suspicious and other roots were the seat of pus. The extraction of this tooth resulted in the disappearance of the supposed parotid carcinoma. Another case was that of a young girl of 19 years, who was in bed for 11 months with polyarthritis and immovable joints. Extraction of a molar with apical abscess was followed by improvement and in a few months she was restored to useful life. Except for slight stiffness of the right knee, she was normal.

Dr. ROBERT T. MORRIS of New York said that the objection made constantly by many good dentists was that they did not wish to destroy thousands of dollars worth of good work to follow out theories. Many of the best dentists did expensive, beautiful work, and patients also were unwilling to have the work interfered with. The physician had to contend this point. On the other hand, one might go to extremes in ordering too many teeth pulled out. There were, fortunately, dentists of such good experience and judgment that the matter might be left to them. It was extremely important for the doctor to choose such a man, who possessed the proper degree of knowledge and who could be depended upon to exercise the judgment required in the case.

Dr. BEVERLEY TUCKER of Richmond, Va., said he was interested in the incidence of Raynaud's disease with oral infection. Focal infection was not confined to the teeth. Tonsils and sinuses were also responsible. In 1914 he had made the statement that pellagra was probably due to some focal infection and that it was not, as generally supposed, a dietetic disease. He had never seen, in the study of 1,000 cases, one pellagrin with good teeth. It was necessary to choose a reliable dentist. Dr. Tucker said that he refused to be responsible for his patients unless they went to a dentist in whom he had entire confidence. Another point was that there was a possible connection between focal lesions and Parkinson's disease. It would seem as if dentistry should become a branch of medicine. In the light of the fact that dentists were endangering many lives by lack of knowledge of medicine, this would be the most desirable solution, and no doubt the coming years and increased knowledge would bring it about.

Dr. W. M. SPRIGG, Washington, D. C., said that when the teeth were normal to the eye and yet there was root involvement, the oral surgeon had a distinct procedure to perform. This was amputation of the apex, after careful *x*-ray work. Instead of removing the teeth, the infection could be removed. Importance of teeth, as regards digestive capacity, was very great, and when they could be saved the oral surgeon was the man to do it.

(To be concluded.)

Miscellany.

Venereal Clinics in Great Britain.—The question of venereal diseases is one of the most important, so far as the successful conduct of the war is concerned. No one disease incapacitates and cripples its victims to the same extent. Its prevention and cure are the most difficult problems with which the medical authorities of all the countries at war have to cope. In Great Britain special efforts are being put forth to meet the situation and a National Council for Combating Venereal Diseases has been formed. Medical women in England are taking great interest in the matter and at a recent meeting of the London Association of Medical Women, an account of which is given in the *Medical Officer*, April 27, 1918, Dr. Jessie Campbell gave a description of the work at the clinic for venereal diseases at Guy's Hospital. The patients come from the hospital itself or from outside districts, or are sent by private practitioners. Remarkably few belong to the class of professional prostitutes, many being wives of soldiers or working girls. Three beds and two cots are attached to the clinic and these are used for acute cases, or cases complicated by pregnancy, nephritis, or heart disease, also for those coming from a distance and for children. The Wassermann test is found positive in a large proportion of cases, though often negative in pregnancy and in recurrent chancre. On the whole Dr. Campbell is doubtful how much reliance should be placed on the Wassermann test. Dr. Elsie Chubb said that much attention was paid to prophylactic treatment in men, while women were left altogether out of account and this one-sided treatment would not help to eradicate the disease. Lady Barrett thought that patients having had gonorrhea should not be admitted into general maternity wards even if apparently cured, as the disease often lighted up unexpectedly.

Two Months in the San Juan de Dios Hospital.—Dr. Gomez, a prison physician of Almeria, has taken a sort of postgraduate course in the famous Madrid hospital, which is said to be the first urological and syphilitic institute in point of age in the world, and relates his experience in *El Siglo Medico* for May 4. At the head of the urological service is Dr. Pulido Martin. First to be mentioned is chronic gonorrhea, the difficulty of curing which is proverbial. Credit is given Fuller and his American colleagues for pioneer work on the part played here by the seminal vesicles. The relationship between infection of these bodies and gonorrheal rheumatism is mentioned. In the San Juan de Dios this teaching is in full swing, and is apparently fully indorsed by the medical staff. Direct endoscopy with Luy's endoscope is practised; on account of the difficulties of internal illumination a simple urethroscope with external illumination is preferred to the cystoscope. The author saw a method in operation which he had not before heard of, a lamp being introduced into the rectum as an adjunct to the cystoscope in the bladder. In this method, which can be applied in women by placing the lamp in the vagina, the field of illumination is applified and lesions in the rectovesical septum can be brought out.

SOME POINTS IN THE MANAGEMENT OF DISEASES OF THE HEART.

BY EDWARD E. CORNWALL, M.D., F.A.C.P.,

BROOKLYN, NEW YORK.

LOOKING back on his own experience and the practice of others as it came to his notice, the writer gets the impression that failure properly to prescribe rest is a mistake in cardiac therapeutics which happens frequently and therefore he will begin these brief remarks on the management of diseases of the heart with a few words on the use of rest in those diseases.

The first principle in the use of rest in heart diseases is to give it in a sufficient dose, and if a mistake is to be made to make it on the safe side by giving too much rather than too little; for giving too much rest rarely does harm to a cardiopath, while failure to give enough may imperil his chance of recovery or improvement; of all remedies the bed is the least harmful in overdose.

The full dose of rest means the horizontal position—feet in bed and head on pillow; and revolution of the body permitted only on its horizontal axis; and no debate on the bedpan question; and the sitting position allowed only when there is orthopnea.

Just how long a patient should remain in bed after compensation for the horizontal position has been apparently restored is not always easy to decide. In chronic valvular disease of inflammatory origin, occurring in adults, the writer's rule is to keep the patient in bed for at least one month after such apparent recovery. In the case of children, his rule is to keep the patient in bed indefinitely, that is, to refuse to set a definite time for getting up. It usually happens that if no such date is set, the patient will be kept in bed about long enough, for the parents usually will connive at disobedience of orders when the child has appeared well for a considerable time. Keeping a child in bed for a long time does him no harm, and it safeguards him to a considerable extent from recurrences of his original disease and starts him in training for the disciplined and restricted life which may be his lot.

In acute endocarditis absolute rest in bed should be maintained for at least three months after symptoms of the acute disease have passed away, whether or not signs of cardiac insufficiency were present.

In acute myocarditis and acute myocardial degeneration the length of time to which the rest in bed need be prolonged depends on the pathological changes in the heart, which changes cannot be accurately made out; but in any case in which pronounced signs or symptoms of myocardial degeneration were noted, the period of rest should be measured in months. In the mild cases which occur regularly in typhoid fever and give no pronounced symptoms, confinement in bed for at least two weeks after defervescence is usually sufficient; but in those cases of typhoid which show unduly rapid pulse, or in which a transient mitral regurgitant murmur is observed, the rest in bed should be continued several weeks longer, and the getting up made gradually and cautiously, and a close watch kept on the behaviour of the heart during the process; if the pulse shows an excessive increase of rate on getting up, the patient should be put back to bed and kept there for several weeks before trying it again. In cases in which there has occurred a sudden dilatation of the heart it may be necessary to keep the patient in bed for many months. The writer has seen persistence for months and even years of irritability and weakness of the myocardium, manifested by tachycardia and shortness of breath on slight exertion, which seemed to be referable to undue haste in getting out of bed after an apparently moderate typhoid.

In diphtheritic myocarditis prolonged rest is highly necessary and even if no special signs of cardiac involvement have been noted the heart should be safeguarded by at least several weeks absolute rest in bed after apparently complete recovery; and if such signs have been observed, three months' stay in bed may be considered the minimum requirement, with special restriction of activity for a subsequent period of not less than a year.

The simple pneumonic heart, without direct inflammatory involvement, presents an imperative indication for absolute rest, although as a rule, for a short period only; in uncomplicated cases the patient can usually be allowed out of bed by the twelfth day after defervescence. During the active period of the disease the patient should be watched constantly or, if that is not practicable, should be restrained, so as to prevent his sitting up or getting out of bed in delirium. A valuable prophylactic in the management of the heart in pneumonia, which the writer has brought out in previous publications, and one which he takes the present occasion to refer to again, is constipation: the use of cathartics is avoided almost entirely. This prophylactic constipation is made possible first, by a special diet, limited in quantity, which discourages with an unfavorable culture medium the growth of the swallowed pneumococci and the putrefactive bacteria in the alimentary canal; and, second, by avoidance

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

of medication capable of disturbing that canal.

In uncomplicated influenza absolute rest in bed from the beginning of the disease until three days after disappearance of the last symptom referable to the influenza, should be the rule. Observance of this simple rule is the best safeguard against the cardiac and other complications of influenza, especially in the aged. As a corollary to this rule might be added extreme conservatism in the use of the coal-tar derivatives, abuse of which is so common.

In conditions of chronic myocardial degeneration with cardiac insufficiency, particularly in the aged, it may be advisable to modify the indicated dosage of rest in order to meet the requirement of keeping the remaining sound fibers of heart muscle in good working order by exercise. It is a common teaching that old people with weak hearts should not be kept in bed for long periods if it can be avoided. This teaching has a certain amount of force, but it should not be made too much of; and when the question of keeping in bed an aged patient with chronic myocardial degeneration comes up for decision, the danger of hastening a cardiac downfall by permitting too much activity should be very carefully weighed against the danger of weakening the heart by too much rest; and it is usually safest to allow the former the preponderating influence. Certainly one or two weeks in bed to enable a therapeutic test of myocardial efficiency to be made by noting the amount of recovery of function, is a safe enough procedure. The possible bad consequences of prolonged rest in bed can be counteracted to a certain extent by massage, passive motions, and resistance exercises.

The restrictions of activity required in cases with fragile compensation or diminished myocardial reserve power play an important part in the management of heart diseases, but their discussion will be passed over with a reference to the general rule, that in all such cases the patient should keep his activities well within the limits of safety, and not try to find out by experimentation just how far he can go. The writer is in the habit of saying to these patients: The better you feel the more careful you must be, for when you feel badly you will be careful anyway, but when you feel well it is natural to be more careless.

The department of cardiac therapeutics which has to do with modification of the diet to meet cardiopathic requirements is one of obvious and great importance. In all cases of cardiac insufficiency more or less passive congestion with its disturbances of tissue metabolism is present, and this constitutes a requirement that the food be easy of digestion and also that it be of a character to safeguard as much as possible the subnormally resistant tissues from injury by toxemias of dietetic origin. Animal flesh and its derivatives, and eggs are common sources of these toxemias, and their exclusion or restriction is therefore indicated in the cardiopathic diet. Milk, however, in some form or other, is generally admissible, and thus the requirement that a considerable proportion of the protein ration be animal protein can be satisfactorily met. Milk possesses all the nutritional advantages of flesh with some others, and is free from most of the disadvantages of the latter. Milk is pre-eminently an easy food, both as regards its protein and otherwise. In this connection it is interesting to note that milk is the specially prepared food which the mammals provide for their young during the immature period following birth. It differs from all other varieties of animal food which contain protein in that it sours when it spoils, thus insuring for its protein a certain amount of protection from putrefaction; the other varieties of animal food containing protein, viz., flesh and eggs, putrefy when they spoil. Herein appears an argument supplied by nature for milk as the ideal source of animal protein in the *easy diet*, and a confirmation of the clinical fact that a diet which favors the growth of the acidophilic bacteria in the alimentary canal is easier on the organism than one which favors the growth of the bacteria of putrefaction. Nature knew what she was about when she made this easy food for the young of the mammals in their weak and immature period, and we can with advantage apply her teaching to the construction of an easy diet for adults who are weakened by disease or age.

In advanced conditions of cardiac insufficiency, with notable crippling of the digestive apparatus or extensive congestion of the liver or kidneys, a temporary reduction of the diet to thin cereal gruels, modified milk and fruit juices may be required; and when much edema is present limitation of the fluid intake is a reasonable procedure; but the dry diet need not be carried to such extremes that the daily fluid intake is reduced to less than thirty or forty ounces. The "Karrel diet" owes part of its success to its non-putrefactive character as well as to its reduction in quantity.

In acute inflammations of the heart, especially in the young, which usually occur secondarily, the primary condition as well as the cardiac complications call for a very easy diet; but after convalescence has been established, it is generally advisable to feed up the patient so as to secure as rapid a restoration to health of the cardiac tissues as possible; but a liberal diet does not necessarily mean one containing large quantities of animal flesh, although a moderate amount of animal flesh is desirable in order to tempt the appetite, stimulate digestion, and exercise and develop the protective mechanism. The diet in these cases should include an abundance of milk and its products, a small amount of animal flesh and eggs, and a wide range of selected fruits, vegetables, and cereal foods.

In the chronic myocardial degenerations, which are usually accompanied by other degenerative conditions calling for dietetic regulation, the indicated diet is a lactovegetarian one or approximately such. In the less advanced cases, particularly in patients who possess a superior tolerance for the protein poisons in question, a small amount of animal flesh or eggs two or three times a week is usually allowable; but the general proposition holds. In all cases of myocardial degeneration the number of meals should be increased and their size made small, and the evening meal should be a light one.

In the treatment of what is commonly known as cardiovascular disease regulation of the diet is the most important thing; and it is one of the greater satisfaction of the practice of medicine

to watch the improvement in patients with this disease which so often follows the taking of a suitable diet. In the early high tension cases dietetic regulation alone may bring about a restoration of the blood pressure very nearly to the normal; and in the more advanced ones it usually brings at least temporary improvement. Lowering of high blood pressure, persistent elevation of which is regularly compensatory, can be brought about most advantageously by diet, and the reduction thus obtained is salutary and does not interfere with vital circulatory necessities; and also, to a certain degree it indicates the extent of the pathological changes which called for the high pressure.

In the prophylaxis of cardiovascular disease the value of dietetic regulations along the lines above suggested cannot be too much emphasized. It is reasonable to expect that in the medicine of the future, which will be largely preventive, this phase of prophylaxis will receive a wider recognition than it now enjoys. Hitherto preventive medicine has been occupied chiefly with safeguarding against invasion of the body tissues by pathogenic organisms belonging to low forms of life; but the safeguarding of the body from unnecessary wear and tear in the processes of nutrition is likewise of fundamental importance.

In any diet due regard must be given to the saline elements of the food. This phase of the subject may acquire special importance if for any reason the diet for a considerable period has to be much restricted in quantity or variety. When abundant milk, fruit and vegetables are taken the necessary salts are usually provided; but when the diet is scanty or lacking in variety it may be necessary to add directly some of these salts, particularly those required to maintain the alkaline reserves in the body. It seems to be a necessary condition of the life of the tissues of the human body that they be continually bathed in an alkaline fluid, and this condition would seem to hark back to the time when man's remotest unicellular ancestor began life in the ocean: the body fluids are still maintained as solutions not very dissimilar to sea water. The salts of sodium and calcium are particularly important, and they should be directly added to the diet whenever there is doubt that enough of them is being supplied by the natural articles of food taken, or when insufficiency of the carbohydrate ration invites acidosis. The question of vitamines need cause no anxiety if plenty of milk, fruit, and vegetables are taken.

Mechanical forms of treatment, particularly formal exercises, massage, and baths, have been made much of in cardiac therapeutics. Passive motions, resistance exercises, and massage may be particularly useful in the period between recovery of compensation for the horizontal position in bed and the acquisition of sufficient reserve power by the heart to make it safe for the patient to get out of bed. But the exercises should be carefully controlled so that the educational and developmental effects on the heart muscle are produced without overstrain.

The therapeutic baths of most renown are probably those which for more than a generation have been exploited at Nauheim. No doubt the war has seriously impaired their popularity, but it would seem that they have been much overrated; and James Mackenzie is on record as saying that their reputation is out of proportion to their merits.

In connection with the subject of therapeutic baths it may be proper to allude to the dangers of cold baths to patients with organic heart disease who are not habituated to their use, and especially the dangers to such patients of bathing in the sea or swimming.

In the management of diseases of the heart the question of when and how to use heart stimulant drugs comes up sooner or later, because the diseased heart is always either functionally insufficient or liable to become so. The scope of this paper does not permit detailed discussion of those drugs, but a few general remarks may be allowed.

The general rule for using heart stimulant drugs is to use them only when rest alone cannot restore the balance of the circulation; but there are exceptions, viz., they may be used to forestall decompensation which seems imminent; and they may be used without delay in cases which are obviously too bad to be restored by rest alone.

The general rule about their dosage is to use enough to produce the desired effect, but not to keep up an excessive dosage after that effect is obtained; and the corollary to this rule is to watch out for toxic effects and not to try to get improvement faster than nature is able to bring it about. Ability to use heart stimulants without abusing them is one of the marks of an expert therapeutist.

Of the direct heart stimulants included in the pharmacopœia two stand pre-eminent, and their action as observed clinically is so like that they can be used to a large extent interchangeably. One of them, digitalis, is universally known and appreciated; the other, strophanthus, is not quite so well known. The writer has studied the effects of strophanthus clinically for many years, and has published his views on its use, and has made this inference from his observations, that to get the best results with it the doses given should be considerably smaller than those recommended in most of the text-books. Strophanthus has the advantage of possessing in its active principle strophanthin, the most uniformly reliable and the most powerful and quickly acting agent of the digitalis class. In regard to the administration of strophanthin, the writer would like to say a word. The intravenous method of administration has been especially commended, and justly; and the hypodermic method has been objected to by some influential writers because of severe pain caused by the injections. The present writer wishes to say in favor of the more convenient hypodermic method, that his observations do not confirm altogether the statements regarding the severe pain caused by the injections. In some of his cases severe pain was complained of, and in some others considerable local irritation was noticed; but in many cases no complaint was made, or at least did not reach the writer. Of course the injection should be given deeply, and the solution made as dilute as the size of the hypodermic syringe permits. The sublingual method of administering strophanthin has also been found by the writer a convenient and effective one.

In connection with these two pre-eminent heart stimulants there are three other drugs which de-

serve special mention, viz., strychnine, caffeine, and morphine. These three drugs may not act as direct stimulants to the cardiac muscle as do digitalis and strophanthus, but they can be very efficient helpers in improving the circulation, and particularly morphine. Our appreciation of morphine in the treatment of the severer forms of cardiac insufficiency increases with our growth in clinical experience.

In concluding these brief, but it is hoped suggestive, remarks on the management of diseases of the heart, the writer would like to refer again for special emphasis, to that fundamental and universal remedy in diseases of the heart, rest. This remedy is so simple, so safe, and so easily applied, and the indications for it are so obvious, that one might think comment on it supererogatory; but the writer's impression that it is not sufficiently used is so strong, that he offers no apology for bringing it up for discussion.

THE PLACE OF IPECACUANHA IN THE TREATMENT OF AURICULAR DISEASES.*

By LOUIS FAUGERES BISHOP, A.M., M.D.,

NEW YORK.

CLINICAL PROFESSOR OF HEART AND CIRCULATORY DISEASES, FORDHAM UNIVERSITY SCHOOL OF MEDICINE, NEW YORK CITY; PHYSICIAN TO THE LINCOLN MEMORIAL HOSPITAL.

One of the most unique circumstances of the treatment of cardiac conditions is that nearly all practical measures are founded upon clinical observation rather than upon what might be inferred from experiment in the physiological laboratory.

The question is, how does a diseased heart react to a particular remedy? It is well known that digitalis reacts in an entirely unique way in the presence of disturbance of the function of tonicity of the heart muscle, and in the presence of a disturbed physiology of the auricle.

A discovery that is founded upon laboratory observation can be immediately accepted by the medical profession and applied without any discussion or debate. A discovery founded upon clinical inference must always be a matter for speculation and question by many observers and holds its place only by very insecure tenure. Later on the laboratory may discover the basis for the remedy, and then it takes its place in established practice. In this way ipecacuanha has been used for many years in the treatment of dysentery, while only of late has the discovery of the ameba put it upon a definite basis.

There is hardly a drug more frequently prescribed than ipecacuanha, though physicians are not really conscious of how often they use it. It forms an essential ingredient of the rhubarb, ipecacuanha, and soda combination that is the standard remedy for all undefined functional stomach disorders in the clinics of New York City. It is used in the form of Dover's powders, because physicians know that this is a remedy that gives relief under varying circumstances.

In the treatment of cardiac conditions ipecacuanha has naturally been used as an adjunct in this way and it has also been used by many as an emetic with the idea of terminating attacks of palpitation. Of course, the belief has been that the effect upon the auricular functional disorders was purely reflex.

The clinical observations which I wish to submit to this society and to the profession and for therapeutic experiment is that in disorders of the auricle, which I believe are very often of toxic origin, ipecacuanha seems to be a valuable adjunct to digitalis. It is the experience of every heart specialist that he is called to very seriously ill people who are suffering from fibrillation of the auricle. These persons are critically ill and have not had proper treatment. There is often not much time to spare and a remedy must be pushed to a degree that is, to say the least, bold. Where the circumstances were very desperate indeed and the medical attendance very inadequate, I have often felt obliged to order digitalis given until vomiting has actually been produced. On one occasion where I was afraid that when the vomiting of digitalis came it might do harm, I combined some ipecacuanha with my digitalis so as to increase the nauseating quality of the prescription in case the digitalis nausea should be postponed too long. To my surprise this condition responded more than usually well to the treatment and I was led to do the same thing on other occasions. One general practitioner was so impressed with the result that he told me afterwards that he had used the mixture of ipecacuanha and digitalis with surprising effect in a very serious emergency.

I am too much of a therapeutic critic to do more than suggest that others repeat the observation. Nevertheless, I have lately been combining ipecacuanha with digitalis in those conditions which I believe to be due to toxic influences, acting upon the auricle. I have been using a tablet containing powdered digitalis, $\frac{1}{2}$ grain, and powdered ipecacuanha, $\frac{1}{8}$ grain. My expectation that nausea would be hastened has not been realized, but the effect of the digitalis seems to me to be improved.

In a person with an untreated fibrillation, the pulse being very rapid and irregular, I ordered:

℞ Pulv. digipuratum, gr. xviii
Pulv. ipecacuanha, gr. v
M. Fiant. pulv. No. xii

Sig.: One every four hours until four are taken; one every six hours until four are taken; and one every eight hours until four are taken.

That there is a definite effect from ipecacuanha on the heart and blood vessels has been recognized by authorities on therapeutics. In Bastedo's work on "Materia Medica and Pharmacology" (1918, page 565), under the heading of effect on the circulation, we find:

"There is a weakening of the heart muscle with slowing and dilatation similar to that from chloroform and not influenced by atropine or cutting the vagi. Death may result from auricular and ventricular fibrillation. In the frog or turtle heartblock has been observed. From therapeutic doses there is a very short and slight rise in arterial pressure, followed by a sharp fall and a general return to its former level. From toxic doses there is a progressive weakening and slowing of the heart and a fall in pressure with collapse. Pellini and Wallace obtained no change or a slight contraction of the

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

arteries; but Evans, Middleton, and Smith say there is a transient vasoconstriction followed by a definite vasodilatation."

We all agree that ipecacuanha is a drug with active physiological and therapeutic qualities. It has definite relations to the functions of the blood-vessels. In large doses it is capable of doing much harm. In this it is like all our valuable drugs. It has certain analogies to digitalis which suggest it as an adjuvant. As to the value of my observation of its therapeutic value in this instance that must be confirmed by clinical observation much wider than one man can obtain.

109 East Sixty-first Street.

A CLINICAL STUDY OF THE VARIABLE THERAPEUTIC POTENCIES OF THE GALENICALS, AND THEIR INHERENT UNRELIABILITY.*

By HENRY BEATES, JR., M.D.,

PHILADELPHIA, PA.

The title of this brief contribution seemingly justifies the opinion that the writer belongs to that group of discontents classified as hypercritical if indeed not iconoclastic, and yet, when conditions governing Materia Medica, in so far as the galenicals are concerned, are seriously contemplated, it is believed that the briefly outlined imperfections and shortcomings will be recognized as facts that cannot be denied.

If this be true it may activate the inauguration of a widespread movement for the correction of defects that continue to impair the and efficiency of the galenical armamentarium, and ultimately result in securing for the clinician medicaments known to possess a uniform standard of physiological potency and therefore means to an end upon which reliance can confidently be placed.

During the past several years, and at the present, consultations in the field of circulatory, renal, metabolic, and nutritional disorders force recognition of the fact that too commonly galencials are prescribed, properly named, but of unknown potency or value, and failure to obtain logically anticipated results is almost the rule, notwithstanding their administration in the usual but conventionally adopted doses.

These experiences recalled to mind a study of the galenicals, conducted many years ago which consisted in subjecting oneself to a severe or thorough physiological experimentation with several specimens or groups of tinctures; thus five specimens of tincture of aconite were obtained from five different but reputable pharmacists, and so with tincture of belladonna, tincture of nux vomica, tincture of strophanthus, and tincture of digitalis. The infusion of digitalis was also investigated. This study was followed with a similar investigation with the chief active principles of these drugs respectively.

Emphasis is made of the fact that in Nature, the crude drug possesses active principles in vastly varying percentage proportions, and hence it must follow that the galenicals prepared therefrom must be characterized by the same variations of therapeutic power with the qualifying difference, however, that these several principles themself differ in solubility in the menstruum employed in manufacture.

Not infrequently they are also associated with other active principles in such proportions as seriously to interfere with the administration of a sufficient quantity of galenical to obtain that principle effect for which it is desired.

The testing of physiological activity was begun at 8 P. M. The conventionally adopted dose, for obvious reasons, was repeated at 40-minute intervals, and it was no little surprise to discover that as physiological effects failed to be secured and the doses therefore were carefully increased, quantities necessary to obtain positive results had to be taken that, prior to the experiments, would have been regarded as toxic, if, indeed, not lethal. Thus tincture of aconite root varied from 4 or 5 of the conventional two to five minim doses, to as many half-teaspoonful or 30 minim doses, before the characteristic slowing of the pulse, respiratory oppression, gentle diaphoresis, numbness or tingling of the peripheral sensory fibers, and the somnifacient effects were obtained. The local sensory disturbance from contact with the lips and tongue were caused before these were experienced in the extremities. Tincture of nux vomica varied from the conventional 15 to 20 minim doses to two teaspoonfuls hourly or every 40 minutes for 4 or 5 doses before the stimulation of the motor columns of the cord and the tension of the flexors of the legs were caused. Tincture of belladonna was the least variable, and conventional doses repeated, however, 3 or 4 times, were necessary to effect dryness of mouth, flushed face, augmented pulse rate, mydriasis, and interference with accommodation.

Tincture of strophanthus was conspicuously feeble in its action upon the heart, and, frequently before this characteristic action was secured, it was necessary to discontinue its use because the other associated active principles caused gastric disturbance, nausea, vomiting, and diarrhea. It could be taken in teaspoonful doses 3 or 4 times in the 4 hours with the certainty of causing gastrointestinal troubles, and a failure to markedly stimulate the circulatory system. With some specimens these wide differences in potency and effects did not obtain, and this instance serves to emphasize the variable therapeutic potency of the galenicals generally.

Tincture of digitalis like strophanthus was surprisingly variable, and to obtain the circulatory effects, doses were commonly so large and repetition so frequent that gastric disturbances occurred and compelled discontinuance. These tinctures were set aside and a year later again subjected to a like test. This demonstrated a fact to which, if generally known, no serious attention is practically accorded, namely, and keep this well in mind, that galenicals in a year's time lose from 20 to 60 per cent. of their original therapeutic potency, whatever that may have been. No wonder, then, that some tinctures of aconite root and of nux vomica could be taken with perfect safety hourly for 4 or 5 consecutive doses, of from 30 minims, ½ a teaspoonful, of the former to 2 teaspoonfuls, 120 minims, of the latter.

Recognition of these facts resulted in abandonment of the galenicals and the prescribing of those

*Read at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

active principles for which the various tinctures were classified as for illustration, circulatory depressants, circulatory stimulants, spinal stimulants, mydriatics, somnifacients, spinal depressants, etc.

It is because of the prevalent conventional prescribing of galenicals at the present hour, and a knowledge of their unreliability that these remarks are submitted for your consideration. Suffice it to state that frequently when in consultation and confronting impending death from decompensation, and seeing the victim edematous, dyspneic, and sorely distressed, and taking conventional doses of tincture of digitalis or the infusion, or perhaps strophanthus and the ever-present consort nitroglycerin, digitalin, Germanic so called, or crystalline strophanthin administered in adequate doses would restore lost circulatory equilibrium, dissipate the anasarca and pulmonary edema and reestablish renal function. Practically a useful and moderately active life was thus restored and, *with continued treatment*, prolonged for years, as experience has demonstrated and proven over and over again.

Search for the causes of this great variation in therapeutic potency discovered several, and among the principal will be first mentioned the long-established commercial evil, to wit, the employment of cheap and therefore inferior crude materials. What this means will be understood when the fact is made known that, for illustration, belladonna leaves were purchased at from 40 cents to 2 dollars the pound. Governmental regulation of this evil is suggested. Regarding this fact further comment is not required. Another and important cause was and largely is the absence of accurate methods of manufacture.

Reference to the Ninth Decennial Revision of the U. S. Pharmacopœia demonstrates this fact, and while there are evidences of an attempt to produce galenicals of approximately standard degree of potency, the latitude of variation is too great to render practicable, on the part of the practitioner, that accuracy of administration which depends upon a constant standard strength.

As galenicals are today, it is imperative that the clinician, in order to obtain positive and unquestioned results, *test the particular medicament he is administering* and thus learn and known what definite effects a given dose, other things being equal, will certainly accomplish.

Let us examine into why such care is essential by every physician for every tincture employed.

The U. S. Pharmacopœia directs for tincture of aconite root that 100 mils of the tincture should yield not less than .045 Gm. nor more than .055 Gm. of either soluble alkaloids (plural) of aconite. What, may it be inquired, *are* these alkaloids, and, how do they respectively affect the human organism?

Concerning tincture of digitalis it is directed that *if* assayed biologically, the minimum lethal dose should not be greater than .006 mil of the tincture or the equivalent in tincture of .0000005 Gm. of ouabain for each gramme of body weight of frog. Of this tincture .5 mil or 8 minims is the dose officially recommended. Here it may be remarked that, ouabain as prepared in sterile ampoules by a reputable manufacturing firm and marketed in boxes containing special directions as to the hypodermic administration of this supposedly powerful medicament, and cautioning that none but experienced clinicians should use it, and not repeat a dose until after several hours had intervened, was found to be inert in 4 times the dose recommended. Inquiry of the writer after a year had passed elicited the answer that the ouabain supplied was unreliable and practically worthless. The assertion was then volunteered that reports from clinicians who used the drug were such that the manufacture of ouabain had been discontinued.

Tincture of gelsemium is directed to be prepared by percolation, using 100 grammes of crude drug and sufficient menstruum to make 1000 mils. Nothing is mentioned as to alkaloidal composition or strength of this galenical product. Tincture of nux vomica is to yield not less than .237 Gm. nor more than .263 Gm. of the alkaloids (plural and undesignated) of nux vomica. The menstruum for this tincture is composed of 3 volumes of alcohol and one volume of water, adjusting the finished tincture so that each 100 mils contain .25 Gm. of the alkaloids (plural observe) of nux vomica.

Tincture of opium should yield not less than .95 Gm. nor more than 1.05 Gm. of anhydrous morphine. What, may it be asked, of the other several principles present in variable percentage in each unit of the crude drug, and variable as to solubility respectively, in the menstruum used? These citations are self-explanatory and careful consideration must render it evident that the crude methods of manufacture must necessarily result in the supply of galenicals that vary in physiological activity as well as in the more or less associated alkaloidal and glucosidal components, as each unit of crude material employed happens to be composed.

Another cause for unreliability and variable potency is the *large quantity made at one time*, and the consequent age of the galenicals we see on the shelves of every pharmacy.

Not only is there a process of disintegration or some form of change that in time results in a loss —in a year's time, as above remarked, of from 20 to 60 per cent. of the original potency, but other conditions undoubtedly also contribute to this deterioration, such as exposure to light, temperature, and variations of humidity.

For generations clinicians have rested content to prescribe galenicals and administer them in conventional doses: If beneficial results were apparently secured they were content; if not, they likewise were content and enjoyed comfort in the belief or delusion that the failures were due to conditions which were beyond relief. It seems never to have occurred to them to ascertain with absolute certainty whether the galenical administered was a physiologically active preparation, or a tincture made of 40 cent. the pound crude drug, or of the 2 dollar the pound.

I venture to state that, at the present hour, if 25 physicians each wrote for the same galenical, and the prescriptions were compounded by 25 different pharmacists, there would be no two alike; furthermore that scarcely one of the 25 clinicians would attempt to familiarize himself with the potency of the tincture prescribed. How the use of active principles arose conjecture alone explains, but has not the almost unexceptional fear to administer them in *adequate* doses, and for *a sufficiently long period of time* resulted from the want of accurate knowledge of the galenicals?

Why do the text books still advise, as well as the almost universal prescribing of inadequate doses continue?

Aconitine is given in doses of from 1 500 to 1 250 gr., strophanthin in similar dose, digitalin (Germanic) from 1 100 to 1 60 gr., although of late years we occasionally encounter a recommendation of 1 30 to 1 10 gr., scopolamine gr. 1 200, and so on. No wonder that experience, based on such almost impotent quantities, has caused the profession to be reluctant about the administration of active principles and to consider them useless.

To emphasize this fact reference is had to digitalin (Germanic), digalin, and strophanthin, physostigmine, hyoscine or scopolamine, gelsemine, etc. For years numerous patients dying of cardiorenalvascular disease, dying while subjected to treatment with galenicals, after having the designated active principles administered, taken in the order named in doses of from gr. $\frac{1}{4}$ to gr. $\frac{1}{2}$ 3 or 4 times daily, and in emergency conditions 3-grain doses hypodermically in 20 c.c. normal salt solution, and from gr. 1 90 to gr. 1 120 3 or 4 times daily, have been restored to a fair degree of health and enabled for years, *during which time these medicines were more or less constantly taken*, to comfortably lead a moderately active and useful life. The much-feared comulative action did not occur. In collapse in pneumonia, as in major operations, digitalin in normal salt solution has succeeded frequently.)

The advantage of prescribing that active principle for which a galenical is selected, rests upon the fact that the numerous associated principles composing the crude drug are eliminated and many objectionable results thereby avoided.

In this age when the best and thoroughly reliable means to an end are a *sine qua non* for victory, is it not strange that the great profession of medicine remains content to rely upon an armamentarium that has been handed down from generation to generation, with apparently none, or at the best very feeble, efforts at betterment. Does not the practice of the present hour too commonly consist in prescribing this or that galenical in conventional doses? Is it a matter of surprise that the laity apparently too frequently obtain, as the expression is, just as good if not better results from osteopathy, neuromechanotherapy, chiropractic, napropathy, and other numerously named forms of massage, as from doctors?

If our viewpoint be true, has not the time arrived for the effort to be exerted for establishing scientific methods for the manufacture of medicine that will possess a uniform and standard degree of physiological potency?

This involves correction at the very beginning, and demands the cultivation of medicinal plants; the gathering of the parts used for the production of reliable and active preparations, their manufacture in quantities that will insure against age, *i.e.* too long keeping and thus avoiding deterioration and relative uselessness; the keeping of finished products in environment that will not militate against their inherent efficiency, and, above all, the development and perfection of processes involved in manufacture, that will supply remedies of a reliable and standard degree of potency.

When these essential conditions will have become established, therapeusis will arise to the plane it should occupy in the world of Science, and its equally cultivated art will win from the public at large that confidence and trust which a truly scientific and skilled profession will merit.

260 South 16th Street.

THE THERAPEUTIC ACTION OF OUABAIN STROPHANTHIN GRATUS.*

By ERNEST ZUEBLIN, M.D., F.A.C.P.,

CINCINNATI, OHIO.

ASSOCIATE PROFESSOR OF MEDICINE, UNIVERSITY OF CINCINNATI, OHIO; RESIDENT MEDICAL DIRECTOR, CINCINNATI TUBERCULOSIS SANITARIUM

In the treatment of cardiovascular disease a great amount of experimental work and clinical investigation has been undertaken for the purpose of ascertaining the therapeutic action and individual indications of the different substances recommended for the relief of the subjective and objective symptoms of these patients. Our knowledge has widened particularly as regards the different alcaloidal principles of the digitalis group, whilst strophanthus tincture has not been so extensively investigated, and in the opinion of leading clinicians, such as Osler,[1] Dieulafoy,[2] Anders,[3] Forchheimer,[4] Hirschfelder,[5] plays only the rôle of a more or less doubtful substitute when digitalis preparations have failed in their therapeutic action. In the course of the past years, however, the general opinion has changed, and a glance at the transactions of this society of the past years reveals the awakening interest for the usefulness of strophanthus and the active substances such as the strophanthins. The valuable contributions of Satterthwaite,[6] Cornwall,[7] and others are well remembered, and, without entering into a closer discussion of their papers, their studies have acted as an incentive for further clinical investigations.

A few introductory remarks may precede my casuistic contributions. Since Fraenkel and Schwartz[8] introduced in our pharmaceutical armentarium strophanthin as a valuable remedy, much work has been done, but as in other domains in science the enthusiastic reports of one particular remedy have been outweighed by less favorable and later reports. Some of the authors have warned against the indiscriminate use of such preparations, which medication even has been considered as the cause of fatal results (Hewlett,[9] Hochheim,[10] Chauffard,[11] Vaquez and Lutembacher[12]). The unstable action of the strophanthus preparations has been attributed to the various mixture of the active substances, and the aim of securing a more reliable product by extraction of the strophanthus seeds has been fully justified (Thoms, Fraser,[13] D'Arnaud,[14] Catillon[15]). The official strophanthus preparations are obtained from *Strophanthus kombe*, as well as Kombe strophantin and its allied crystalline strophanthidin. D'Arnaud in 1888 first isolated a crystalline product which, derived from the *Strophanthus gradus*, he called the gratus strophanthin or ouabain, which he considered identical to the ouabain isolated from acocanthera. The crystalline form of the ouabain considered as a guarantee for its purity, its definite solubility, and the comparatively rapid absorption, a small or no tendency to cumulative action have

*Paper presented at the annual meeting of the American Therapeutical Society, Richmond, Va., June 7-8, 1918.

been mentioned as an explanation for its most active qualities (Rowe[16]), compared with the strophanthin derived from the kombe strophanthus. Strophanthin kombe is understood to be a mixture of a crystalline and an amorphous acid strophanthin, differing markedly in their quantitative physiological activities, whilst ouabain is only one crystalline product. It must be remembered, however, that different samples of ouabain contain variable amounts of water of crystallization, a fact which seems to render its uniform activity doubtful. We must leave the final discussion of these differences to the experienced chemist and pharmacologist.

From the clinical standpoint the task is to ascertain the therapeutic value of a new remedy on the sick patient. Only a scant literature on the subject of ouabain is available. For further reference I would call attention to the papers of H. C. Bailey,[17] Catillon,[18] Vaquez et Lutembacher,[12] the last two contributors dealing with the French preparations. In an interesting study Bailey made on 47 cases at Bellevue Hospital, he recommends ouabain for intramuscular administration in a concentration of 1:4000 saline solution, while for intravenous use the concentration is from 1:6000 or 1:8000, the maximum initial dose for the first 24 hours being from 0,00025-gramm (Vaquez et Lutembacher) or 0,0005 gramm according to Bailey. In the opinion of the last named author the crystalline strophantin-ouabain is considered as a valuable cardiac stimulant in cases of broken compensation, in chronic interstitial myocarditis, as well as in any form of chronic valvular disease. Ouabain as a remedy for cardiac emergencies ought to be used only by intramuscular or intravenous injection. It is not suited for continuous use and must be given under strict medical supervision or undesirable results will be the consequence. The dose should not be repeated within 24 hours and a repetition must be dependent upon the results of the first injection. Vaquez advises an interval of from three to four days between the different doses, which measure appears justified in doubtful cases. It is of interest to study this author's opinion of the use of ouabain d'Arnaud, and it is generally admitted that the active principles formerly used in the arrow poison of the Pahuins (Pelikan et Vulpian[18]) is a distinct heart poison which under certain circumstances also affects the striated, as well as the smooth, muscular fibers. Acting upon the heart muscle proper, it is supposed to render the slowed heart contractions more vigorous and also to increase the amplitude of the ventricular diastole. This action, interpreted as a selective one bearing directly upon the myocardium or by an intermediate effect upon the nervous system of the heart proper, seems to reestablish the impaired tonicity and contractility of the myocardial structures. Clinical evidence seems to substantiate these claims, particularly in instances of extreme cardiac insufficiency, attended by acute dilatation, pulmonary edema, and marked stasis in the portal system. As these manifestations may rapidly disappear under the use of ouabain, the result is more striking if previous to the cardiac stimulation a moderate venesection has been practised in order to relieve the extreme distention of the right heart, so permitting a more rapid contraction of the cardiac muscle.

Yet unexplained is the interesting relation of ouabain to the subsequent better effect of a digitalis therapy. While digitalis, when applied first, would only in exceptional instances give any results at all, it appears to become reactivated when given subsequently, or it will keep up effectively the primary favorable results of the ouabain medication. Cases are on record which show this effect for weeks or months afterward. The action of the ouabain upon the vessels, if any, can be admitted, is only slight; an action upon the renal functions is not conspicuous. The recommendation of Danielopoulo[19] and others may be recorded advising the combined administration of theobromine or of nitroglycerin with ouabain, the latter in instances of attending hypertension. It is claimed that the only signs of intolerance consist in nausea and vomiting (Hochheim, Chauffard, Vaquez) which may be the result of an overdose and may be avoided by a more careful administration of the drug. While using ouabain, as well as strophanthin, we must not forget the marked irritative qualities of that drug when brought in contact with injured tissue, leading to marked inflammation of the latter, even to abscess formation. Therefore deep muscular injections into the gluteal muscles are advisable, but these may become quite painful within a half hour of the administration. Bailey's advice of subsequent massage of the injected muscle is reasonable, since pain and irritation can so be avoided. Also when resorting to intravenous administration one must avoid varicose veins, for such inelastic vessels are more easily injured leading to perivascular infiltration. Supposed the intravenous administration is the method of choice, the needle should enter the vessel in its longitudinal axis, so to avoid a pricking and injury to the opposite vessel wall, leading to an undesirable periphlebitis. The occurrence of chills following the intravenous and intramuscular introduction of the drug, mentioned by Fraenkel and Schwartz and Bailey must be regarded as a rare occurrence. Hewlett's observation of heartblock following the use of strophanthin is not the only observation so far published, Vaquez and Lutembacher admitting such a possibility, however, they mention instances in which arrhythmias existing before the ouabain medication were corrected and were absent after the treatment, for which peculiar occurrence no explanation has been given as yet.

Although in my hospital work I have had no opportunity to control the therapeutic action of ouabain by a series of pulse and cardiographic tracings, as published in the papers of Bailey and Vaquez and Lutembacher, my observations have been restricted to the study of pulse, blood pressure, size of the heart, ascertained by palpatory percussion, the character of the heart sounds, and the record of the symptomatic subjective complaints of the patients so far studied. Notwithstanding these handicaps of instrumental records, some information may be abstracted from my case study.

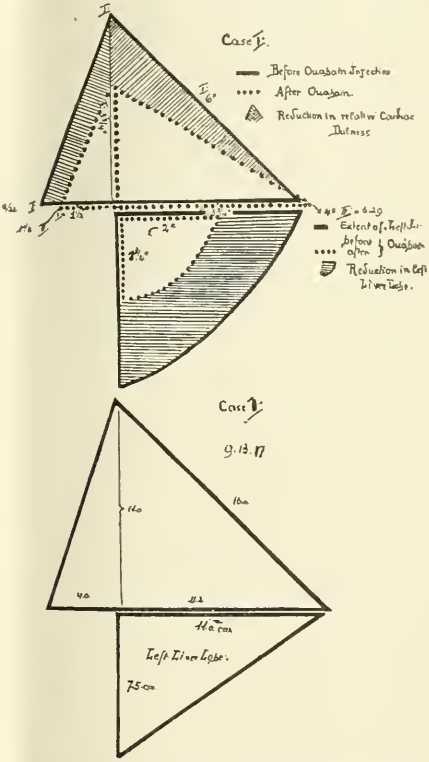
The ouabain preparation at my disposal were the sterile ampoules containing the crystalized substance in a dilution from 1:4000 of sterile saline. The contents of the ampoules, assayed pharmacologically corresponded to 0.0005 gramm of the active crystalline body; the injected dose varied from one to two cubic centimeters, given intramuscularly or intra-

venously. With the exception of one case, the injection was in all instances well borne. In one instance (Case II) a perivascular infiltration was noticed for several days much complained of by the patient on account of pain and swelling. As a rule the patients were kept at absolute rest in bed, with liquid diet in restricted amounts, keeping the patient as far as possible from exertion or nervous or other excitement. Since in my practical work I encounter so many cases of myocardial degeneration complicating or coexistent with pulmonary disease, the clinical study of these cases was of much interest in the hope of learning the effect of ouabain in such cases. We all are aware that in pulmonary tuberculosis with a chronic more or less fibrous process the heart reaches a stage in which all or most of the cardiovascular stimulants known are unable to supply the asthenic and toneless myocardium with the necessary contractile power to fight successfully against the intrinsic and extrinsic obstacles of impaired circulation.

As in other publications upon ouabain therapy, my study deals with cases of valvular, endocardial, and myocardial insufficiency. Such a subdivision is justified by various reasons, etiologically and objectively, for from the standpoint of prognosis and treatment these cases offer distinct differences.

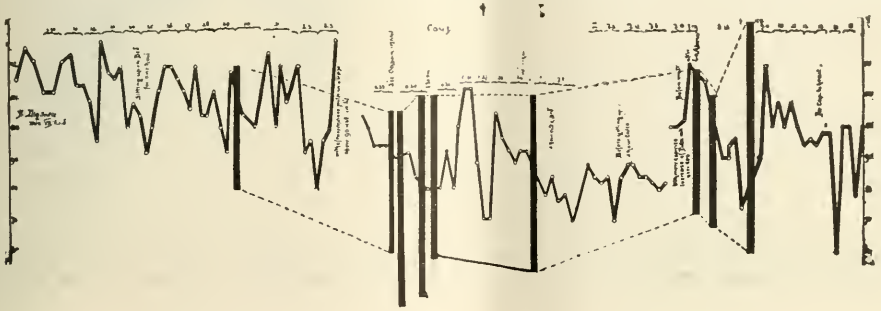
Of the cases of valvular lesions with incompensation the following are reported:

Case I.—J. McD., colored boy, age twelve years, admitted January 2, 1917. The family history was negative. He complains of persistent cough for past three weeks with anorexia, but no symptoms suggestive of a cardiac condition. Physical findings on admission: well nourished, slight subfebrile temperature not in excess of 100.8° F., marked tachycardia, oscillating from 128 to 192 at rest, considerable dyspnea, respiration at rest 42 to 44 per minute. Chest: bulging precordium, diffuse apex beat extending from the fifth intercostal space over an area 2 inches in diameter toward the axilla and the sternum. Distinct thrill over apex. Relative cardiac dullness: 9.4 cm. to left, 3.7 cm. to right from the midsternal line. Transverse diameter 13.1 cm. Upper border of third intercostal space overlapping the right Sternal border 1.3 cm. Height 9.3 cm.—xiphoid process to upper border of third rib. Oblique diameter 12 cm.; cardiac triangle of relative dullness 60,915 square centimeters. Auscultation in fifth intercostal space reveals a double murmur, involving systolic and diastolic phase, harsh, blowing, transmitted toward the posterior axillary line, considerable shortening of systolic-diastolic interval. First tricuspid sound substituted by blowing murmur, second pulmonic sound and first aortic sound normal, distinct murmur replacing the second sound. Pulse rate, at rest, 120, fair volume, fairly regular; ascending wave sudden, succeeded by rapid fall (Corrigan pulse), volume fair. Lungs: impaired percussion over both apices, as far as first intercortal space anteriorly and third intercostal space posteriorily, on right side, to upper third of scapula on left side. Inspiratory sounds harsh, a few inspiratory crepitant rales; accentuated, prolonged expiration, pronounced pectoriloquy coincident with extent of percussion changes. Right base anteriorly, below the seventh intercostal space posteriorly, impaired percussion note, distant respiratory sounds, no movable dullness present. Liver dullness



considerably enlarged, especially of the left obe extending far below the xiphoid process and toward the left hypochondrium. Increase of liver consistency, surface smooth, slightly tender on pressure. Urine high specific gravity, no albumin nor casts. Sputum mucoid, negative for tubercle bacilli on repeated examination; diplococci and *Bacillus catarrhalis* present, few lymphocytes and mostly neutrophile cells.

Symptomatic treatment of patient's cough, enforced bed rest for three weeks following admission. Cardiac



stimulation consisting of tincture of digitalis 8 minims, t. i. d. Blood pressure, 10 days after start of digitalis: systolic 120 mm., diastolic 80 mm., pulse pressure 40 mm. Hg.; pulse rate 104, cardiac activity pro one minute 21,600 mm. Hg.

Pulse rate, notwithstanding the digitalis medication, persisted in being high, only on the fourth day falling to 94. The least exertion caused rapid and very irregular pulse, persisting several days following the sitting up of the patient. Blood pressure readings were in accordance with the unstable pulse rate. Average pulse rate 128 to 90 heart beats. On June 22: persistent enlargement, 9.5 cm. to left from midsternal line, 3 8 cm. to right; transverse diameter 13.2 cm. Height 9.7 cm; oblique diameter 15.5 cm.; surface of cardiac triangle, 64.02 square centimeters. Absolute bed rest was ordered. An injection of 2 c.c. of ouabain intravenously into the right arm, causing no trouble nor later inflammatory symptoms.

Blood pressure preceding injection found at systolic ausculatatory reading 105 mm. Hg., diastolic 40 mm., pulse pressure 62 mm. Hg., pulse rate 90, cardiac activity per one minute 13,320—considerably lower than on the former occasion. On the following day considerable lessening of pulse rate was noticed, a drop reaching 94 to 90 and 84 in the evening. The bloodpressure on the following day registered systolic 110 mm. diastolic 46 mm., pulse pressure 64 mm., pulse rate 84, cardiac activity pro one minute 13,304—just slightly less than on previous occasion. Pressure readings the same day in the evening: systolic 110 mm., diastolic 48 mm. Hg., pulse pressure 62 mm., pulse rate 80, cardiac activity per one minute 12,640—the lowest figure so far encountered in this instance. The pulse quality was softer, ascending wave far better sustained, regular, no more extrasystoles nor irregularities present. The change in the cardiac size is seen from Chart I. 10.2 cm. to the left 3.8 cm. to the right from the midsternal line, transverse diameter 14 cm. Height 6.1 cm., oblique diameter 14.4 cm., cardiac triangle of relative cardiac dullness 42.7 cm., demonstrating a reduction of 21.62 square centimeters or 33.7 per cent. less than 24 hours before. Whilst the right ventricle had mostly contracted, the left ventricle suggested a slight displacement to the left with a marked reduction in the height of the heart. As a further consequence of the ouabain action the reduction in the extent of the left liver lobe will be noticed. The lateral diameter of the left liver lobe was 5.1 cm., corresponding to a reduction of 4.5 cm., the distance from the xiphoid process was 4.8 cm. or 4.1 cm. less than on the former occasion. Considering the left liver triangle we have a reduction of 30.48 square centimeters or 35.09 per cent. We are permitted to think of a considerable relief in the portal stasis.

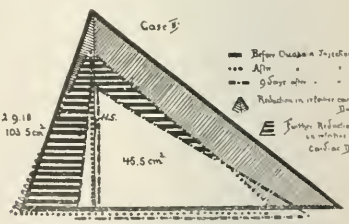
The apex beat was less diffuse, more forcible in its action. A lessening of the mitral murmurs, their softer nature, a lesser radiation toward the axilla became manifest. The tricuspid murmur, softer in character, was still noticeable in the anterior axillary line, greater accentuation of the second pulmonic sound and added to the same a soft diastolic murmur over the pulmonic as well as over the aortic area must be recorded.

For the following two days the pulse rate fluctuated between 92 and 80, after that the irregular rate and frequency with an occasional rise to 112 on June 26 was noticed. After June 28 the pulse rate was reduced gradually to 94—88 on June 29. Pressure readings on the same date gave for systolic 110 mm., diastolic 54 mm. Hg., pulse pressure 56 mm., a pulse rate of 72, cardiac activity 11,808 mm. The further contraction of the heart was found 10.2 cm. to the left, 2.9 cm. to the right from the midsternal line, transverse diameter 13.1 cm., height 4.8 cm., oblique diameter 11.9 cm. The cardiac triangle of relative dullness corresponding to 34.44 square centimeters showed a reduction of 31.58 square centimeters or 49.3 per cent., as compared with that before the ouabain was given, 15.6 per cent. being added to the reduction recorded 5 days previous. Later, however, a tendency to dilatation of the cardiac muscle was anticipated, showing that ouabain may give a fair immediate, but not always persisting, reduction in the size of the heart unless the medication is repeated or followed up by a protracted cardiac stimulation. The left liver lobe maintained its reduced size, extending 5.1 cm. to the left from the midsternal line and 4.5 cm. below the xiphoid process, the left liver triangle corresponding to 11,475 square centimeters, demonstrating a reduction of 31.25 square centimeters, or 73.1 per cent., an addition of 38.1 per cent. to the former measurements. The heart sounds were rougher, more intense in character, the murmurs could be traced over a larger district than on the previous examination. After June 30 a slowing of the pulse rate was noticed, the maximum being 88, the minimum 70. Gradual exercise was permitted, but on each occasion a considerable increase of the rate up to 120 a minute was the result, with a lower reading of both systolic and diastolic pressures.

The patient did not receive any further cardiac medication, the high pulse rate persisting while the patient's exercise was unrestricted. A marked rise of the systolic pressure 134 mm., diastolic pressure of 60 mm., pulse rate 74, cardiac activity 14,356 mm. Hg., or an increase of 24.7 per cent. over the minimal activity was the result. Two months later the following cardiac diameters were found: 11.2 cm. to the left, 3.8 cm. to the right from the midsternal line or transverse diameter 15 cm., height 11.1 cm., oblique diameter 16.3 cm., cardiac triangle of relative dullness 61.05 square centimeters, only 2.97 square centimeters less than before the ouabain medication, representing 4.63 per cent. below the first measurements.

In résumé we may say that in this instance the ouabain medication was followed by a temporary improvement in the reduction of the size of the heart, in the slowing of the pulse, in the rise of blood pressure, the considerable relief of dyspnea, the reduction of the left liver lobe, the improvement of the manifest stasis in the portal system. In order that these valuable and rapid changes may be persistent we must give careful supervision to the case and further cardiovascular stimulation through digitalis and allied preparations, guarding the patient against recurrences from cardiac dilatation; for this, if overlooked, may mean lasting damage by exhaustion of the cardiac reserve strength.

Case II.—Mrs. F. E., colored, age 27 years, single, cook. Family history negative. After an operation of cystic goiter in September, 1917, she suffered from anasarca, dyspnea, and cough, with abundant mucoid expectoration. After treatment for several weeks at another institution patient improved, but since February, 1918, has been confined to bed on account of cardiac failure attended by considerable anasarca, dyspnea, and bloody expectoration. Admitted to our hospital on February 9, 1918.



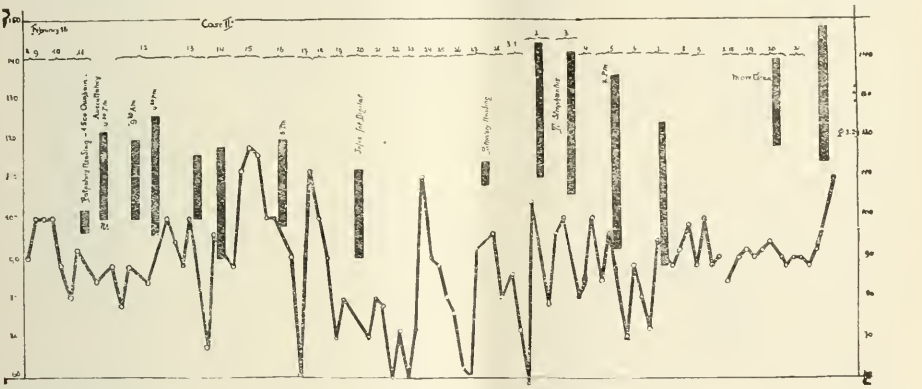
Physical findings on admission, very stout patient, sitting in upright position, very dyspneic, cyanosis of lips, considerable anasarca of upper and lower extremities, abdomen distended by fluid. Heart examination: apex beat diffuse in sixth interspace, outside of midclavicular line, relative cardiac dullness 14 cm. to the left and 4 cm. to the right from the midsternal line, height 11.5 cm. Oblique diameter 22.5 cm. transverse diameter 18 cm. Area of relative superficial cardiac dullness 103.5 square centimeters. Heartsounds: First mitral sound indistinct murmurish in character, second sound indistinct; first tricuspid sound indistinct and distant; second pulmonic sound booming and markedly

accentuated; aortic sounds nothing abnormal. Pulse very rapid and irregular, 100 a minute. Pulmonary findings: Extensive pulmonary stasis with numerous moist and diffuse rales. Sputum examination negative for tubercle bacilli, diplococci present. Urine: trace of albumin, several hyaline and granular casts.

The patient was kept under absolute bedcare, liquid diet, ice bag being applied over the heart. Tincture of strophantus, 10 minims t. i. d., given for the next two days. The pulse had become a little slower, but on February 11 the blood pressure reading, obtainable only by the palpatory method being very low—102 mm. —diastolic value was not obtainable. Ouabain solution (1.5 c.c.) was injected intramuscularly. Three hours later the bloodpressure readings obtained on the left arm by the ausculatory method were 122 mm. systolic, 100 mm. diastolic, pulse pressure 22, pulse rate 84; cardiac activity pro one minute 18,648 mm. The patient felt more comfortable; she was less embarrassed in talking, less dyspneic, the night being more restful. The following day at the site of injection of the left arm a moderate swelling and tenderness was noticed, so the bloodpressure readings refer to the right arm. At 9 A. M., 18 hours after the injection, the pulse rate was 88, systolic reading 120 mm., diastolic 100 mm., pulse pressure 20 mm., cardiac activity pro one minute 19,360 mm. Twenty-four hours after the injection the pressure registered over the same area 126 mm. systolic, 96 mm. diastolic, pulse pressure 30 mm., pulse 84, cardiac activity 18,648 mm. As it was still in excess and exceeding the one hundred mark, especially noticeable after the least excitement of the patient. On February 20, nine days after the ouabain injection, the pressure was found at 112 systolic, at 90 mm. diastolic, pulse pressure 22, the pulse rate 108, cardiac activity 21,816 mm. Hg. pro minute. The diameters of the relative cardiac dullness were as follows: 12 cm. to the left, 1 cm. to the right from the midsternal line, representing a transverse diameter of 13 cm., a height of 7 cm., an oblique diameter of 15 cm. The triangular area of the relative cardiac dullness comprised 45.5 square centimeters.

These results compared with the former findings evidently suggested a considerable change in the size of the heart which could be noticed very soon after the injection of ouabain had been given. Also with regard to the blood pressure readings the difference could not escape attention, since the auscultatory pressure readings were possible only after the injection.

This case is of particular interest since ten days after the first treatment we tried the patient's cardiac function whilst under the influence of an infusion of 15 grains of powdered digitalis leaves in 6 ounces, a dose of 1 dram being given t. i. d. The patient at first did not tolerate the medication very well, as vomiting occurred, attended by a very weak and irregular pulse, and pressure readings were obtainable only by the palpatory method on February 27. On March 2, the pulse was found stronger, rate 104, systolic pressure 144 mm., diastolic 110 mm., pulse pressure 34 mm., cardiac



desirable to watch the exclusive action of the ouabain injection, all other cardiac medication was discontinued. Two days later the systolic pressure had declined a little, 116 mm., the diastolic reading was found at 100, leaving only 16 mm. for the pulse pressure with a pulse rate ranging at 100, cardiac activity pro one minute of 21,600 mm. Hg. Evidently the heart was working excessively with the imminent danger of cardiac failure.

Three days after the ouabain injection the size of the heart was found reduced, relative cardiac dullness extending 9.5 cm. to the left, 4.7 cm. to the right from the midsternal line, representing a transverse diameter of 14.2 cm., or 3.8 cm. less than on the previous examination. The height measured 9 cm., or 2.5 cm. less, the oblique diameter was found at 14.8 cm., or 7.7 cm. less. Taking in account the area of the relative superficial cardiac dullness representing 63.9 square centimeters, or 39.6 square centimeters, or one-third less than on the previous examination. On auscultation the mitral murmur replacing the first sound was more manifest and radiated further toward the left axilla; the second pulmonic sound was still markedly accentuated, aortic sounds indistinct.

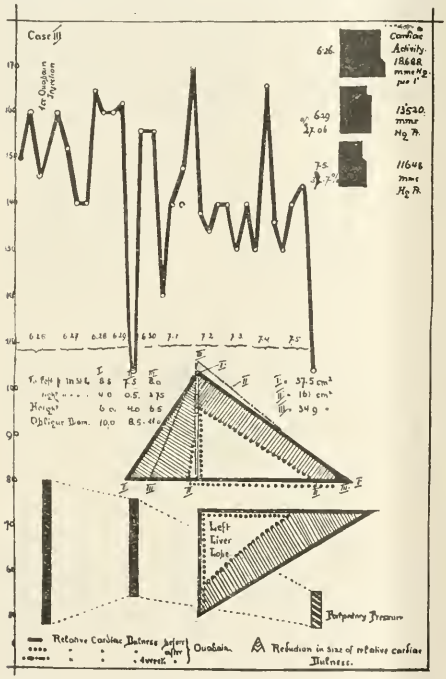
The blood pressure readings on the same day revealed for the systolic reading 118 mm., for the diastolic 90 mm., the intermittent 1, easily depressible pulse rated at 96, cardiac activity pro minute 19,968 mm., a figure far above the normal cardiac function.

As seen from the pulse chart, the pulse rate was activity 26,416 mm. Hg. pro minute. On that date the digitalis medication was dropped and substituted by tincture of strophanthus 10 minims t. i. d. In the course of that medication there occurred a slightly lessened pulse rate attended by a lowered systolic as well as diastolic pressure. At a later period (three weeks later) both pressure readings became higher, particularly the diastolic readings remained above 100. The anasarca which at first had receded, increased again, causing considerable distress to the patient, who required the administration of morphine, gr. ¼, and atropine, gr. 1/120, for the temporary relief from the marked dyspnea. The patient died on March 29. The postmortem examination revealed atheromatous degeneration of the aortic valves, chronic endocarditis of the left ventricle, besides thickened bicuspid valves, myocardial fatty degeneration, chronic passive congestion of the liver, gallstones, chronic congestion of the spleen, chronic interstitial nephritis, moderate hydrothorax, hydropericardium, a few chronic adhesions of the right pulmonary apex and ascites.

Case III.—E. M., white girl, age nine years, admitted June. 26, 1917. Incomplete history obtainable from mother of child relative to acute onset of disease with chill and fever three weeks ago.

Physical findings: White, female patient, very exhausted and dyspneic, sitting in upright position, cardiac region bulging, diffuse apex beat in fifth interspace, in midaxillary line. Relative cardiac dullness extending 8.5 cm. to the left, 4 cm. to the right from

midsternal line, transverse diameter 12.5 cm., height 6 cm., oblique diameter 10 cm., cardiac triangle of relative cardiac dullness 37.5 square centimeters. Distinct thrill present over cardiac area. Heart action rapid, pounding second pulmonic sound. Diffuse moist gurgling rales all over the chest render the interpretation of the cardiac sounds very unreliable. Pulmonary findings of congestion and diffuse bronchitis with stasis over both bases. Marked cyanosis of lips and upper extremities. Left liver lobe markedly enlarged, extending 10 cm. to the left from the midline and 6½ cm. below the xiphoid process. Blood pressure: systolic 80 mm., diastolic 48 mm., pulse pressure 32 mm., pulse rate 146, cardiac activity 18,688 mm. Hg. pressure per minute. The patient when first seen was given immediately one intravenous injection of 1c.c. of ouabain. The patient stood the injection very well, apparently feeling relief from the extreme cardiac distress. The following changes in the extent of the cardiac dullness were recorded the next day. Transverse diameter 8 cm., 7½ cm. to the left from the midsternal line. ½ cm. to the right from the midsternal



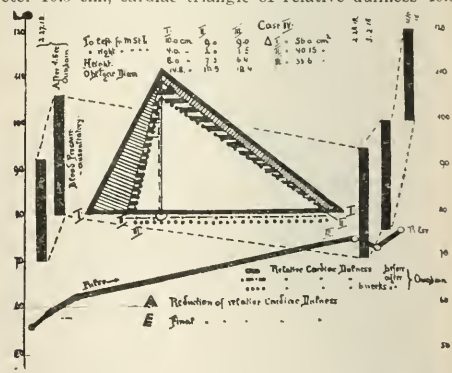
line, height 4 cm., oblique diameter 8½ cm., cardiac triangle of superficial dullness 16 square centimeters, or 21.5 square centimeters less than on the preceding day. The heart sounds were better sustained, but no murmurs could be detected. The left liver lobe extended 5 cm. to the left from the midsternal line and 4½ cm. below the xiphoid process. The pulse was still frequent, ranging at 140 per minute, showing a slight reduction in the rate. The pulmonary findings revealed a moderate improvement with less moisture, but still pronounced harsh, almost tubular, breathing over both apices.

One week later without any further cardiac stimulation the heart showed the following size for the relative dullness: Transverse diameter 10¾ cm., extending 8 cm. to the left, 2¾ cm. to the right from the midsternal line. Height 6½ cm., oblique diameter 11 cm., cardiac triangle of superficial dullness 34.93 square centimeters, a figure only 2.6 square centimeters below the first measurements obtained. The pulse was hardly perceptible, 138 per minute, only palpatory blood pressure readings could be made; systolic pressure was 56 mm., diastolic 48 mm., with a pulse pressure of 8 mm. The patient was very uncomfortable and dyspneic, probably also on account of the more marked pulmonary stasis. This patient developed symptoms of poliomyelitis and consequently was transferred to the neurological service of our city institution.

It must be added that on June 29—three days after the ouabain injections—the pulse rate was found at 104, with a systolic pressure of 76 mm., a diastolic reading of 54 mm., a pulse pressure of 22 mm., a cardiac activity pro one minute of 13,520 mm. The clinical impression of this case treated with ouabain was not very favorable since, notwithstanding the considerable reduction in the size of the heart following the medication, the dilatation noticed one week after, suggested that evidently the heart had not sufficient strength to cope with the difficult task of overcoming the increasing venous stasis.

In several cases of myocarditis without valvular lesions ouabain medication was tried, and a few instances may be briefly recorded.

CASE IV.—J. B., age thirty-five years, machinist, was suffering from active pulmonary tuberculosis involving both upper lobes and the base of the right lower lobe. Sputum at various examinations positive. On account of dyspnea and general weakness, the patient's heart examination on February 27 showed the following diameters for the relative cardiac dullness; transverse diameter 14 cm., 4 cm. to the right, 10 cm. to the left from the misternal line; height 8 cm., oblique diameter 14.8 cm., cardiac triangle of superficial relative dullness 56 square centimeters. Heart sounds, with the exception of the indistinct first tricuspid sound, normal. Pulse rate 56 at 10 A. M. Blood pressure, systolic 92 mm., diastolic 70 mm., pulse pressure 22, cardiac activity pro one minute 9,072 mm. Hg. pressure. At 2 P. M. on the same day ouabain solution, 1.5 c.c., was given intravenously, which medication was well borne by the patient. Four hours and a half later the pulse was found at a rate of 58 pro minute, the systolic pressure 106 mm., diastolic 80 mm., pulse pressure 26, cardiac activity pro one minute 10,788 mm., distinctly better than on the former determination. On the following day, the patient being still kept in bed and under exclusive milk diet, the following pulse and pressure readings were found: pulse rate 74, systolic 94 mm., diastolic 70 mm., pulse pressure 24, cardiac activity pro one minute 12,326 mm. Hg. pressure about one-third higher than on the first examination. This result was confirmed by the heart examination four days later, showing a reduction in the transverse diameters of 11 cm.—9 cm. to the left, 2 cm. to the right from the midsternal line; height 7.3 cm. oblique diameter 10.5 cm., cardiac triangle of relative dullness 40.5

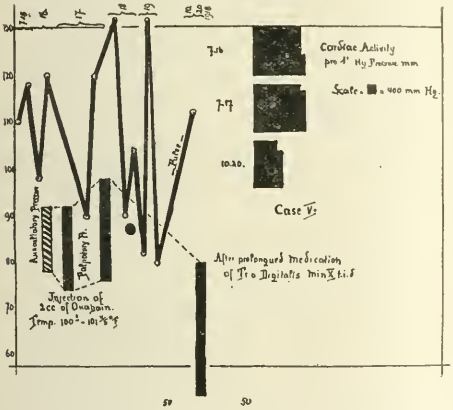


square centimeters, or one-fifth less than on the previous examination. The first mitral sound was better sustained, the first tricuspid sound had become normal. Blood pressure, auscultatory, 100 mm. systolic, 76 mm. diastolic, pulse pressure 24, pulse rate 72, cardiac activity per one minute 12,672 mm. Hg. With the palpa-

tory method higher figures were recorded. The patient felt much better and, the dyspnea having disappeared, was anxious to resume his exercise. This was granted only in restricted amounts. Six weeks after the one dose of ouabain, the patient taking light exercise, the heart had preserved its minimal size, a transverse diameter of 10.5 cm., a height of 6.4 cm., an oblique diameter of 12.4 cm., or a cardiac triangle of 33.6 square centimeters. When last seen the patient's blood pressure ranged at 120 mm. systolic, 80 diastolic, pulse pressure 40, pulse rate 76, cardiac activity per one minute 15,200 mm. Hg.

If in the preceding case the ouabain medication gave a favorable result, it must be admitted that in other instances of advanced myocardial degeneration the therapeutic effect, if obtainable, is not very striking and only temporary. Such instances also occurred in our observation, a few examples of which may be cited.

Case V.—Miss F. E., age 26, suffering from pulmonary tuberculosis involving all lobes for the past seven years. Positive sputum, slight febrile evening temperature not exceeding 101°. Patient is frequently dyspneic even while at rest. Relative cardiac dullness



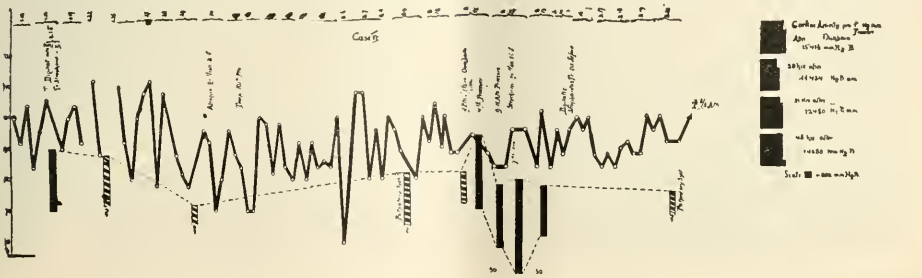
Case V.
Auscultatory Pressure
Palpatory R.
Injection of 2cc of Ouabain.
After prolonged Medication of Tr o Digitalis min X t.i.d

found extending 9 cm. to the left, 0.5 cm. to the right from midsternal line; height 7.5 cm., oblique diameter 11.5 cm., cardiac triangle of relative dullness 35.62 square centimeters. First tricuspid sound split, markedly accentuated, second aortic sound reduplicated, snappy; also reduplication of second pulmonic sound. Pulse 120, irregular, depressible; systolic pressure left arm 92 mm., auscultatory, 78 mm. diastolic, pulse pressure 14 mm., cardiac activity per one minute 20,400 mm. Hg. pressure. Four hours after intravenous injection of 2 c.c. of ouabain, with a pulse rate of 120, the systolic pressure was 92 mm., diastolic 74 mm., pulse pressure 18 mm., cardiac activity per minute 19,920 mm. Hg. pressure. On the following day no difference in the size of the heart could be noticed, the split first tricuspid sound was no more heard, the heart sounds remained forcible. Pulse rate remained the same; systolic auscultatory sound registered at 98 mm., diastolic 76 mm., pulse pressure 22 mm., cardiac activity 20,880 mm. Hg. pressure. There was no further change noticeable as regards the patient's pulse rate nor with regard to the general weakness and dyspnea.

At a later date digitalis medication, 10 minims, t. i. d., of the tincture, had no influence either upon the pulse rate or upon the blood pressure, or on the size of the heart, which organ on *x*-ray examination showed diaphragmatic adhesions and displacement toward the left.

Case VI.—J. L., white patient, tailor, age fifty-eight years, suffering since January, 1917, from chronic bronchitis, which later was diagnosticated as pulmonary tuberculosis with involvement of all lobes. Positive sputum, slight febrile evening temperature, with tachycardia. About January 9 the presence of edema of the lower extremities was found; heart sounds were indistinct and distant, no particular enlargement of the heart, transverse diameter 10.8 cm., 10.3 cm. to the left, 0.5 cm. to the right from the midsternal line; height 7 cm., oblique diameter 11 cm. From January 16 to 22 the patient while receiving tincture of digitalis, 10 minims, and tincture of strophanthus, 5 minims t. i. d., his condition became worse; the pulse was found very indistinct, blood pressure obtainable only by the palpatory method, only systolic reading of 88 mm. being found. On February 9 systolic pressure only was obtained—palpatory 88 mm., pulse 88, patient being kept in bed rest with liquid diet. On February 11 at 1 P.M. the same findings prevailed. An injection of 1.5 c.c. of ouabain was made into the muscles of the arm. Three hours later the pulse registered 94, auscultatory pressure, systolic was 94 mm., diastolic 70 mm., pulse pressure 24 mm., cardiac activity 15,416 mm. Hg. pressure pro minute. At that time the heart sounds had become more distinct, with marked accentuation of the second pulmonic and aortic sounds, apex beat felt inside of the left midclavicular line. On the following day, twenty hours after the medication, the pressure and pulse were recorded as follows: pulse 84, fairly well sustained, systolic 78 mm.. diastolic 58 mm., pulse pressure 20 mm., cardiac activity pro one minute 11,424 mm., and on the evening of the same day pulse 96, systolic 80 mm., diastolic 50 mm., pulse pressure 30, cardiac activity 12,480 mm. Hg. pressure. On February 13, two days later, with a very high pulse rate of 102, the systolic pressure was only 78 mm., the diastolic 62 mm., pulse pressure 16 mm., a cardiac activity of 14,280 mm. After that date an attempt with the same strophanthus-digitalis medication had no beneficial influence whatsoever, edema and anasarca became more manifest, blood pressure readings were obtainable only with the palpatory method, 76 mm. being the maximum found on February 20. The patient died on March 2 from cardiac failure.

So far my observations on cases of acute and chronic endocarditis and a few cases of chronic myocardial degeneration. A few more cases could be added to those already mentioned. However, a great number of observations are required for a conclusion as to the therapeutic value of a new



remedy and in my casuistic contribution only a few points may be mentioned. In the short study we may subdivide the results into those which became evident shortly after the remedy had been given and into the ultimate changes which appeared only later. Furthermore we must be guided by the nature of the pathological lesions, whether they are associated or not with affections of the endocardium, the myocardium, or whether we have to deal with an acute or chronic process with symptoms of a systemic infection.

Among the immediate obvious changes to be expected after ouabain injection we see the improvement of the blood pressure which before could hardly be obtained by the palpatory method and frequently for the systolic value only, once the remedy had been given we could ascertain with the auscultatory method the systolic as well as the diastolic threshold. Under favorable conditions we may expect a distinct rise in the diastolic pressure (Cases I, II, IV) within the first 24 hours, which rise ought to persist for several days over the initial figure. The change in the diastolic pressure is less conspicuous but apparently a reduction in that value may be looked upon more favorably than a rise. Where a tachycardia becomes less, or approaches more normal figures, and where a bradycardia equally approaches the normal rate, this ought to be interpreted favorably. Considering the cardiac activity, cases with a high pulse rate and a low pulse pressure frequently are unfavorable as to the final outcome.

In instances of cardiac hypertrophy and dilatation a considerable reduction in the extent of the relative cardiac dullness can be anticipated (Cases I, II, III, IV), but such a reduction does not mean a constant result nor a definite promise for the effectiveness of the cardiac medication. As seen in Case III, where a high septic temperature complicated the outlook, an initial reduction in the size of the heart would not be maintained against the cardiac overstrain.

Incidentally, with the improvement of the circulation a decided reduction in the extent of the left liver lobe could be noticed (Cases I, II, III).

With reference to the heart sounds reduplicated sounds may disappear and extrasystoles may equally vanish, while cardiac murmurs are not liable to change in character.

The nature of the pathological lesion, whether endocardial, associated with marked hypertrophy and tending toward dilatation, or due to an already degenerated myocardium, has a great bearing upon the final results. The first mentioned instances appear favorable for the use of ouabain medication, particularly when haste is required to stimulate the contraction of the dilated and distended cardiac muscle previous to the effect of digitalis medication which requires a longer time to become manifest.

Wherever we have to anticipate a toxic myocarditis and extensive degeneration—due to age or other factors—we may try the ouabain without expecting too much from it. Just as in other instances where the reserve energy of the myocardium has been exhausted a forceful stimulation of the cardiac muscle may accelerate the fatal issue.

In the cases submitted for discussion it will be remembered that only one dose of ouabain had been given; this was for the purpose of finding out how long this one dose of the drug would show its therapeutic action if such action could be observed. The question arises when and how often can we repeat the dose and with what effect. Other cases are being studied and a later report is anticipated; for the present, however, it seems to me that fresh samples of ouabain very likely deserve our attention from the therapeutic standpoint as a possible means of administering effectively to cases of cardiac deficiency.

PRICE HILL.

PRODROMAL SYMPTOMS OF THE NERVOUS FORM OF ARTERIOSCLEROSIS.*

BY H. CLIMENKO, M.D.,
NEW YORK,
ATTENDING NEUROLOGIST CENTRAL NEUROLOGICAL HOSPITAL, ADJUNCT ATTENDING NEUROLOGIST MONTEFIORE HOSPITAL, CHIEF NEUROLOGICAL CLINIC, MT. SINAI HOSPITAL, O. P. D.

THE intimate correlation existing between the nervous and cardiovascular systems necessarily makes any change in one affect the other. It is extremely rare to find a patient with cardiovascular disease showing no concomitant nervous symptoms; on the other hand, one of the cardinal signs of nervous disease is an altered circulation of the blood in the affected part, as is evident from the frequent so-called trophic changes. Indeed, every normal function is the result of a proper adjustment of these two systems while a dissociation is effective in producing morbid symptoms. To enumerate, however, all the nervous

*Read before the Section of Medicine of the New York Academy of Medicine, May 21, 1918.

phenomena that occur in diseases of the cardiovascular system is not within the scope of this paper. It is also not the aim of the writer to go into the study of focal changes in the nervous system produced by altered conditions of the cardiovascular apparatus as these conditions have been so aptly described by such leading authors as Starr, Thomas, Brooks, Collins, Dejérine, Babinski, Charcot, Binswanger, Oppenheim, and others, and a mere reference to them is all that is necessary.

In this communication I wish particularly to call attention to a chain of symptoms which I believe has hitherto not been described and which I prefer to call the initial syndrome of Windscheid's disease, or the initial symptoms of the nervous form of arteriosclerosis. They occur mainly in people of nervous temperament at or soon after middle age. These symptoms can best be classed under the psychoneurotic type. They consist of a form of excitability, but unlike the usual neurasthenia are not accompanied by exhaustion. As a rule these people have no obsessions or any real signs of mental deterioration. They are able to attend to their work and are at times even brighter than before. They can successfully meet Münsterberg's requisition for a well-organized mind in which the central idea is able to inhibit the opposite and is in no danger of being overrun by any chance intrusion into the mind. Their leading psychic symptoms are introspection, regret, and uncertainty. The patient seems to take a sort of mental balance sheet of his life. He is keenly aware of the mistakes, or what appear to have been mistakes, he has made. He worries over that and often he does things to remedy them which are contrary to his usual psyche. The previously timid and reserved will now become bold and adventurous. It is at this stage that men undertake all forms of disastrous financial speculations. The patient may begin to find fault with his family life; the wife or the children are not exactly what they should be. Quarrels at home are often precipitated on the slightest provocation. The patient attributes all these conditions to a previous lack of foresight, to a mistaken path in life. Numerous plans are created in his mind; every one of them is gone over carefully, only to be thrown aside before it is given a test. When finally a course of action is chosen it may be begun, but each step the patient takes is accompanied by many inconsistencies and it is soon dropped.

These uncertainties often assume an absurd character. Some of these patients will return five or six times and knock at the physician's office door to ask again the same, to them, very important question, "How many times a day should the medicine be taken?" Then the telephone will ring; Mr. B. has forgotten. "Is it before or after meals?"—"and the diet?"

At times jealousy supervenes and then life is a misery to the consort. The Russian novelist Dostoyewski very aptly described this form of jealousy: "It is a jealousy without cause or reason. It is jealousy for the sake of jealousy."

With all this, as pointed out above, the patient attends to his routine work with the same regularity as before and at times even better. He forgets himself in doing his work. Apparently these symptoms resemble *démence lacunaire* but they differ from those of this syndrome as they really do not show any real mental perverseness.

Soon the patient shows subjective somatic changes. Various digestive disturbances such as hyperacidity with increased appetite develop, but in spite of this a noticeable loss of weight takes place. Irregularity of the bowels is frequently a complaint and insomnia is an important and constant symptom. Cardiac palpitations, hot flushes, and a sense of pressure around the precordium are often the leading subjective vasomotor symptoms. At about this time the patient, for the first time in his life, begins to think of death. It was probably at this stage that Solomon exclaimed: "Vanity of vanities . . . all is vanity." It was also at this stage that a modern great writer, Tolstoi, began seriously to consider the problem of the state of being.

With the advent of somatic symptoms the patient comes to the physician. When his confidence is gained the above psychic syndrome in one form or another will be revealed. Examination shows absolutely no demonstrable neurological or psychopathic stigma. All the laboratory tests are apt to be negative. The cardiovascular system, however, shows marked changes. There is invariably an increased blood pressure, somewhere between 150 and 170 systolic and 80 or 90 diastolic. The pulse is increased in frequency, and quite often irregularities are noted. A characteristic of the blood pressure is its inconstancy. It may show wide variations between one visit and another. A few years ago, before I understood this condition, I frequently gave a bad prognosis and sometimes had to change my opinion at the next visit of the patient. In one instance a man of forty-eight came to me with a systolic blood pressure of 180 and diastolic of 100. Naturally, I told his wife that the case seemed to be grave. A week later, to my great surprise, the pressure had fallen to 140 and 80. It rose again afterward, only to come down once more and so continued to fluctuate, continuing in a state of inconstancy with its ups and downs. I have never encountered in these cases a low blood pressure. Frequency of the pulse, too, is not constant. It is always above the normal, from 100 to 120. It may, however, come down to the normal, but I have never seen bradycardia. The irregularities seem also to be of the neurotic type. Only in two cases was an electrocardiographic examination made for me, and in both the diagnosis was "premature systole." The hands, in spite of the frequent congestion, are cold. Hot flushes may be present. Dermographia is not a constant feature. Sargent's white line I have never noted, though I looked for it in all the cases under my care.

The urine of these patients often shows an increased amount of indican; otherwise it is negative. The patients always give a history of having led a strenuous and laborious life. This and tobacco seem practically to be the only real etiological factors. Arteriosclerosis, resulting from alcohol, syphilis, and lead poisoning, so far as my observation goes, does not produce this form of psychic symptoms. If such symptoms are present

they are probably soon masked by the more grave and usual syndrome of cerebral degeneration. The family history in most of these cases shows a neurotic tinge.

The prognosis is good as a rule. When properly handled a relative cure may be expected. I have, however, seen some of these cases go into real cerebral arteriosclerosis, developing the classical triad of symptoms: headache, vertigo, and enfeebled memory, the blood pressure becoming permanently high. Too much emphasis cannot be laid on the precaution against giving a bad prognosis to a middle-aged patient with a high blood pressure, particularly when the uranalysis is negative. Experience has taught me not to tell such patients their blood pressure; it saves me from altering my prognosis and it saves my patients from unnecessary worry. On the other hand, before giving a fair prognosis, alcohol, syphilis, and nephritis should be carefully excluded.

The treatment of these cases is more an art than a science. No single drug or chain of drugs can be recommended. Before discussing what to do, I will outline two rules as to what not to do: (1) Do not take these patients away from their usual occupations, and above all do not send them to the country for rest. They will not rest. Instead, they will brood over their condition and return worse than they were. A merchant whom I had sent to a popular rest resort came hurrying back in a more agitated state than before. "Why, doctor," he said, "this doing nothing will drive me crazy!" He was right. I sent him back to his business and used other means of treatment and he improved. (2) Another thing to avoid in breaking off suddenly their established habits. Do not take away tobacco too quickly. Moderate its use if you can, but demanding complete cessation gave me pretty bad results in one case. The patient suffered so much from his insomnia that he was on the verge of suicide. A moderate amount of indulgence in tobacco relieved his symptoms greatly.

It is certainly advisable to moderate their work, but the treatment par excellence is psychotherapy. I do not necessarily mean psychanalysis. No single system of psychotherapy can be advised. The main object is to gain psychic, or rather moral control of the patient. With intelligent patients the argumentative or reasoning method is efficacious. Here, as probably elsewhere, the straightforward, common sense attitude, accompanied by sincere interest in the patient's welfare, gains ground. It seems to me these people understand their physicians as well as their physicians understand them and sincerity will always win them. A quiet, unhurried, reasoning talk will often make them see that their irritation is unreasonable. I have often seen the blood pressure fall fifteen to twenty points at the end of an office visit lasting about half an hour. Never should an attempt be made to trap these patients into confession. They will invariably tell their innermost secrets when they perceive the sympathy of the physician. Most of these patients are hard-working people who have not had much of life outside their occupations. Relaxation in the form of some hobby or new interests, such as music, social gatherings, and short journeys, is often advisable.

With obstinate or less intelligent patients suggestion in one form or the other may be used. The best sort of suggestion is, of course, the old reliable electricity. At present high frequency is in favor. This, as well as static waves of bygone days, I consider a good suggestive form of therapy. There is no doubt that the blood pressure falls after half an hour of treatment. The patient sits reclined in an easy chair ornamented with attractive brass fittings, listens to the soothing buzzing of the machine and watches the fascinating blue color of the electric sparks. Although the machine has helped on many occasions I cannot say that it is alone of any physical value, since the same results may be obtained by mere rest and a quiet and pleasant chat. Maloney's form of relaxation, accompanied by a good deal of suggestion, is often advantageous.

Drugs in these cases are used only to combat symptoms. The chief symptom to relieve is insomnia. Perhaps I am rather old fashioned, for I use the bromides. In many cases they give me splendid results. Organotherapy, enticing as it is, should be employed sparingly in these cases. The only rational drug of this class would be thyroid. I have used it in a number of cases, but have found it agitates the patient and increases the symptoms as a rule. In women, when there are signs of menstrual changes, I sometimes but not always use ovarian extract with good results. The diet should be that of the usual arteriosclerotic form, but less rigid. I allow my patients eggs, milk, and white meats.

The question may be raised whether we are not dealing here with an involutional form of psychoneurosis. Probably it is an involutional type, but in that event it is due to a vasomotor disturbance which assumes the form of arteriosclerosis.

Another objection may be raised as to the actual arterial changes in these patients. To this I shall only quote Mackenzie. "Our present methods of investigation permit us to recognize organic disease only when the structural changes are fully established. We have no means to determine a disease during the process of its formation. At this stage the only knowledge we may obtain consists of the so-called subjective symptoms." If to this we add the functional changes in the blood pressure that have not been noticed previously, it is fair to assume that we are dealing with a presclerotic stage of the arteries.

The following cases afford a good illustration of this syndrome:

CASE I.—B. S., male, aged forty-nine years, a clothing manufacturer, born in Russia of Hebrew parentage. A significant fact in the family history was that his mother was nervous. He is not alcoholic, denies gonorrhea and syphilis, but indulges in tobacco to excess. He has three healthy children; the oldest, a daughter, is a public school teacher; the second, a son, is a college student, and the third child is still in school. At twenty years of age B. S. came here from Russia, where he had graduated from a gymnasium, intending to study medicine. In America he married a woman of different make-up than himself, a shop girl without any education. He intended to continue his studies in this country, but his marriage and early fatherhood put an end

to his dreams of acquiring a learned profession. He went into business on a small scale and soon became absorbed by his new occupation. His business grew and his entire world was centered in it. Nothing outside of that interested him. To-day he is a man of means with a well-established business. His family has never been of interest to him. In his wife he saw the woman and housekeeper, and there was nothing more in common between them. The children are perfect strangers to him. He always worked until late in the evening in his factory. He was not religious. During the second half of the Sabbath he would either go over his accounts or see people on business.

Present Complaint: During the last few months he has begun to experience a sense of uneasiness. To cite his own words, "Something is not as it should be; something is missing." He nevertheless continued his work. Sleep was slow in coming and was not as sound as before. He smoked more than before, but that only increased his uneasiness. For hours before he fell asleep, he would re-read an old Russian novel that was of interest to him decades ago. About that time a sense of pressure developed over the epigastrium that spread in the precordiun. The old Russian classics brought back childhood and youth memories. His old regrets floated up again. He reflected how different things might have been had he not met his wife, and had he not married. Instead of dealing with waists and quarreling with the Waistmakers' Union, he might have been to-day a leading lawyer or a famous physician. He might have had a wife who would have been a real mate to him. These were the thoughts that kept him awake during the small hours of the night. In the morning he would again go to his business. There, he stated, "I am Master; at home I am a stranger." His wife and children, according to his opinion, looked upon him as a source of income and nothing more. He could see no real filial love on the part of his children. He tried to find enjoyment in cabarets, vaudeville, and finally women, but cabarets looked ridiculous to him; with women he was a failure; they really did not interest him. His symptoms grew worse, particularly his insomnia. There would be sleepless nights with all the accompanying symptoms of insomnia. When he came to me he complained mainly of insomnia, uneasiness, pressure over the heart, and cardiac palpitation. His blood pressure was 180 systolic and 100 diastolic. His reflexes were increased. Wassermann negative. Urine had a sp. gr. of 1020 and, save for increased indican, was negative. I prescribed for him and asked him to return. In a few visits I obtained the above story with a few additional unnecessary details. A gentle, argumentative line of reasoning persuaded him that after all his grudge against his family might be imaginary, and he then quieted down. Advice to become nearer to his wife and children did not have results, for they were of a different make-up from their father. He, however, joined one of the social movements of his race, spending his evenings at various meetings, and, thanks to his intelligence, he became a prominent member in that moveent. While I was unable to reconcile this man with his family conditions, I do believe that the new interest created took him away from his introspection. He soon became more quiet, his insomnia began to disappear, his thoughts were engaged in a different direction. This time it was a hope to see "a people liberated" that seemed to form his main object in life. With the improvement of his psychic condition, his blood pressure came down to somewhere around 140 systolic and 80 diastolic. Only once in a while now he comes complaining of a sense of pressure in the precordium, and very rarely does he pass a sleepless night. For the last six months, I have never seen his blood pressure above 160. His symptoms are apparently gradually passing away.

Case II.—A. J., forty-three years of age, a Russian Jewess, is a woman of good education. One of her sisters suffered from hysteria. She had a practice as a graduate midwife in Russia among a poor Jewish population, then married and in due time gave birth to a daughter. She was deeply interested in the welfare of her people and was active during the first revolution, and she and her husband were sentenced to Siberia. He died on the way in one of the prisons. She managed, however, to escape and came to America in 1905. Here she entered a college of pharmacy and, after graduating, opened her own drug store, but her life continued to be one of struggle. She was absorbed by her child, but managing her store, paying the mortgage, and trouble with clerks and competitors demanded almost all her powers of concentration. At about the age of forty-two she began to be troubled with symptoms of the menopause; hot flushes, restlessness, hyperacidity, and finally insomnia. At that time she first consulted me. Her blood pressure was 175 and 110, pulse 120. Dermographia was present. Urine showed a marked increase in phosphates. Gastric contents showed total acidity 90, free acid 40. Appetite was rather capricious; she ate several times a day, but could never eat a full meal, though she frequently got hungry. Coffee she took in moderation, two cups a day. No tea. During her restless nights, Mrs. G. would think of her wasted life, as she called it. True, she had a child in whom she took pride, but she felt a void. How differently she could have arranged her life, had she married again when she was thirty. She had so many chances. Now she was a woman with a grown up child and could not think of remarriage. She would be ashamed to give a stepfather to her fifteen-year old daughter. She reflected that in two or three years her daughter would marry and then she would be all alone. These thoughts kept her awake at night. I was able partly to combat her insomnia with bromides, and her hyperacidity with small doses of atropine. She also was fed on ovarian extract mixed with small doses of thyroid. Her psychic symptoms could not be managed so easily. On my advice she took short journeys, but they gave her little relief. One day she came to me saying that she had decided to go back to her old ideals. She would labor among the poor working girls and help them in their struggles with their employers. Whether on account of this new interest, or perhaps some additional factor which she did not relate to me, she began to improve rapidly. Her blood pressure came down to 125 and 70. I thought that any further questioning would infringe upon my patient's personal life which had nothing to do with me. I feel that as soon as symptoms disappear, my services are at an end. I believe she is still doing well.

The third case, while unsuccessful from a therapeutic standpoint, is an illustration of the fact that this condition will, if unchecked, go on to actual physical degenerative changes.

Case III.—S. B., fifty-two years of age, a cloakmaker, was born in Russia of Jewish parentage. He took an occasional glass of whiskey before meals and indulged moderately in tobacco. The patient came to me complaining of occasional headaches, dizziness, insomnia, and restlessness. During his sleepless nights he worried a good deal about his wife, an ordinary Jewish working woman who did not look as if she had ever possessed any attractiveness whatever and who considered her husband insane. He believed she was untrue to him and that one of the children was not his. Previously a boarder had lived with them, he himself having invited the man, to relieve the burden of the rent. The child is at present twelve years old. The boarder died two years ago. S. B. had no definite reasons for worry; still, during his restless nights, he recalled scenes of years before, to which he had paid little heed at the time, and out of which he constructed a whole plot where one fact fitted into the other. His blood pressure was 190 and 110. His pulse showed intermissions. The urine was of a specific gravity of 1010. Nothing was efficacious in arresting this man's condition; his health steadily declined until within two years he developed a typical picture of cerebral arteriosclerosis.

Typhoid Fever in Horses.—Of much interest, according to Combes, is the recent discovery that a bacillus very close to paratyphosus B is pathogenic to the horse. Horses may therefore be regarded as possible carriers of clinical typhoid.—*Le Progrès Médical.*

AN IMPROVED OPERATION FOR INTERNAL HEMORRHOIDS.

By WILLIAM LEE SECOR, A.M., M.D., F.A.C.S.,

KERRVILLE-ON-THE-GUADALUPE, TEXAS.

CHIEF SURGEON, KERRVILLE SANITARIUM-HOSPITAL.

THE general practitioner is confronted with few conditions that will cause more acute suffering or that may be the basis of a greater variety of reflex disturbances than internal hemorrhoids. I am of the opinion that the general practitioner, as a rule, pays too little attention to the part played by chronic inflammation in and about the rectum as a causative factor in the production of various reflex symptoms manifested in the genitourinary, digestive or nervous systems.

Very true, hemorrhoids in themselves seldom cause death, but in this day of modern medicine and surgery life and death are not the only possibilities that we must consider in carrying out our treatment of a given case. Efficiency must also be considered. It is not our whole duty simply to save a patient's life by some cleverly performed operation; we must, if possible, restore him to his place in the community as a useful and fully efficient member of society.

Investigation would show that there are thousands of both men and women whose efficiency is greatly impaired by the possession of internal hemorrhoids which have developed to the stage of protrusion. Men who, instead of being able to do a full day's work with comfort, can work only a fraction of the time, and women whose household and social duties become drudgery because of the constant reflex disturbances due to the piles. In the latter, these symptoms are often interpreted as of pelvic origin and local vaginal treatments, copious douching, or even some surgical procedure on the pelvic organs may be instituted for their relief.

The anal canal extends from the levator ani muscle to the skin and is lined in its lower half with squamous epithelium. It is guarded by the internal and external sphincter muscles. The mucous membrane of the lower portion of the canal is thrown into a number of folds called the columns of Morgagni which contain on their interior some muscular fibers, a vein, and an artery. These veins frequently present varicosities in their lower portion and it is in this area that hemorrhoids have their origin. Between these columns are folds of mucous membrane known as the valves of Morgagni, and the pockets formed by these valves are often the seat of inflammatory conditions which frequently end in the formation of an ulcer, abscess, or fistula.

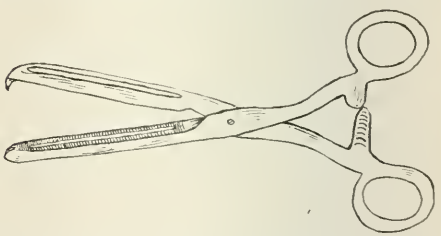
The venous radicals, where these varicosities originate, connect directly with the superior hemorrhoidal vein. This vein is a radical of the portal system and has no valves, which accounts for the tendency to engorgement and formation of the varicose condition which results in internal hemorrhoids. The direct connection of the anal region with the portal system communicates to any infection of this region the most serious possibilities.

If one examines carefully a cross section of a pile tumor one will find that it is composed of dilated blood-vessels with a variable amount of connective tissue around and between them, and the whole mass covered by mucous membrane. In addition to dilated veins each hemorrhoidal tumor is supplied with one or two arteries, branches of the superior hemorrhoidal artery. In large tumors with a single artery this vessel may be nearly as large as the radical artery at the wrist.

In studying the nerve supply of the anus we find a ready explanation for the various reflex disturbances that we have mentioned, for while the movable rectum derives its nerve supply from the sympathetic system, through the plexuses of Auerbach and Meissner, and is scantily supplied with sensory nerves, the anal canal derives its nerve supply from the spinal cord and because of its abundant supply of nerve filaments, is one of the most sensitive regions of the body; its nerves are in close relation to the origin of nerves which are distributed to remote parts.

When we come to consider carefully the methods of treatment for hemorrhoids we will be greatly surprised to find that many men today are using practically the same methods that were in vogue 2000 years ago, for Hippocrates, Galen, and Celsus all used salves, astringents, and excision.

The palliative treatment of acute piles is justifiable, but where the disease process has resulted in organized tumor formation, neither salves nor constitutional treatment will be of permanent benefit,



and some one of the radical operations should be advised.

The injection method is spoken of by Cooke[1] in the following terms: "After viewing the matter impartially from every standpoint, the conclusion seems warranted that it is at best an unscientific and unsurgical makeshift which has been too long exploited at the expense of a credulous public—that it is not without danger in any case and permits no honest assurance to a patient of permanency of cure, should real danger be escaped. If the treatment is carried out after a full explanation on all points, the responsibility may in a sense be shifted to the patient. But while he may possibly soothe his conscience in this way, the surgeon certainly does not uphold the highest ideals of his profession."

At least as far back as 1813 the ligature method was practised and for a short time was very popular in France, but because of bad results fell into disrepute. It still has a number of ardent supporters in America, whose chief argument in its favor is its simplicity. To say the least, the ligature method in its various modifications possesses certain objectionable features which are not in line with modern surgical teaching.

In spite of postoperative pain and frequent hem-

orrhage, the clamp and cautery method is perhaps the most universally used to-day. It has some good features, but if one has ever had a severe secondary hemorrhage following its use, one will hardly care again to trust the sealing of vessels, which may be as large as the radial artery, to a mere crushing and searing process.

The Whitehead operation in spite of the many objections offered to it, is still done by some and in a limited number of properly selected cases is a most excellent procedure.

The clamp and suture method, in which the base of the pile is clamped, its top cut off outside of the clamp, and then a continuous catgut suture introduced over the blades of the clamp, is becoming more popular every day and usually gives very gratifying results. Cooke[1] says, "My personal experience with this method has been highly satisfactory. Considered in comparison with the other methods in common use, it conforms more nearly to the recognized principles of surgical technique than any other with the exception of the clamp and cautery. That it has the advantage of greater security than the latter seems clear; and its relative simplicity is an additional weighty consideration in its favor. As between the two, the clamp and suture method seems on the whole the more nearly ideal." Many other rectal specialists and general surgeons agree with Cooke in giving the clamp and suture method the highest place among the various operations that have yet been devised for the radical cure of hemorrhoids.

The clamp and suture operation as it is generally performed today, while more nearly approaching the ideal than any other is, however, open to one very serious objection in that the needle and suture passing back of the clamp in this very vascular area may carry infection into the hemorrhoidal veins which may give rise to either local or remote abscess formation. The late Dr. John B. Murphy[2], commenting on an improved suture operation which the author had suggested, was very emphatic in his condemnation of the old suture method. He said: "Transfixion of a vein with a suture in a zone grossly subjected to infection, as the anus, should not be done—the day of disaster is sure to come. An ascending infection through the middle and superior hemorrhoidal veins into the inferior mesenteric produces the fatal pylephlebitis."

An ideal operation for hemorrhoids should be free from danger of infection of the hemorrhoidal veins, free from danger of hemorrhage, free from postoperative pain, should approximate the mucosa so as to leave no scar tissue, and should not traumatise the tissues enough to cause stricture. Not one of the old operations meets all of these conditions.

In the *Journal of the American Medical Association* of July 17, 1916, I described an operation which to my mind and in my experience more fully meets all of the requirements of an ideal operation for this condition than anything yet published. Its safety and simplicity cannot help but appeal to every careful thinker and its efficiency can be most readily demonstrated by trial.

After thorough dilatation of the sphincters, the field is painted with 3 per cent. iodine solution, a hemorrhoidal tumor is grasped and put on tension by two hemostats, one at its upper border and the other near the skin margin, then the base is clamped with a special clamp having fenestrated blades similar to the Mayo-Moynihan stomach clamp. The tissue distal to the clamp and in the grasp of the hemostats is now cut off and a number two plain iodized catgut suture armed with a short, slightly curved needle at each end, is used in making a back-and-forth shoemaker's stitch through the slit in the blades, the clamp is then removed and the suture tied. Care should be taken to have the first stitch include all of the tissue of the upper border of the pile tumor, for this will prevent hemorrhage.

In my first operations of this type with the aim of eliminating the one objectionable feature of the clamp and suture method, I tried to use the ordinary Ferguson clamp and place my stitches distal to the clamp. Then I tried the use of two clamps, stitching between them, but found each of these methods very unsatisfactory. Finally I used a Ricard phymosis clamp with fenestrated blades, and for the ordinary case it answers the purpose very well. I later had a special clamp made, it is somewhat heavier and stronger, has slightly curved handles and the tips of the blades are made with a mouse-tooth arrangement that assures accurate approximation of the blades.

There are usually three or four hemorrhoidal masses that should be dealt with in the above described manner, then a strip of iodoform gauze smeared with sterile petrolatum is inserted in the anal canal, to be removed in twenty-four hours and replaced, if necessary to relieve gaseous accumulation, by a small catheter.

The bowels are moved with oil and a small enema on the fifth day and the patient may usually leave the hospital on the seventh day.

In the great majority of cases there is very little or no postoperative pain. There is no danger of infection being carried into the large veins because the veins have been crushed back of the stitches. There is no danger of hemorrhage, for there is no ligature to slip or scab to pull off, and the close stitching readily controls all bleeding; and when in three or four weeks following the operation the rectum is examined, little or no scar tissue is seen, but the mucosa seems perfectly normal.

It is upon these findings which have been noted in a number of operations over a period of four years that I recommend this operation as a simple, safe, and highly efficient procedure applicable to the treatment of a high percentage of cases of internal hemorrhoids.

Repopulation of Germany.—The Reichstag is concerned with two problems, viz., venereal diseases and Malthusianism, which threaten the birth rate. It is recommended to get the workers away from the cities, where they can have small detached cottages in which light and country air and nutritious food can be obtained. This course would tend to increase the number of births. It has been learned that about half of the mutilated soldiers are marrying women older than themselves, a custom which is pernicious for repopulation. To check infant mortality more children's clinics will be established.—*La Presse Médicale.*

Military Medicine.

Medical Problems of Aviation.—Bernard (*Le Progrès Médical*, May 11) enumerates some of the aspects of aviation which belong to the province of the physician. First he mentions the effects of flying on sight and hearing. Next comes the reaction of the nervous system and psyche—the nervous tension and subconscious fear of falling especially within enemy lines. The aviator has many activities—pursuit, observation, bombing—and he must possess coolness, quick wit, and prompt decision. When not on the wing his life is one of forced idleness, to balance the intense and prolonged labors of the day, or night. Strange to say, it is not always the robust man, the open life man, or the sporting man who makes the best flyer, although the qualities which such men possess are always of value.

It is now easily seen that there was an enormous waste at the outbreak of the war through imperfect and unsystematic selection of pilots. This meant loss of both man and machine power. The shortcomings under this head have now been met by various resources. There are now schools of apprentices and much trying out can be practised—adaptation to altitude, adaptation to cold, and all other prophylactic subjects come into play to determine the fitness of candidates. We know now that the aviator temperament is the great asset. Such a man takes naturally to the technique of the machine no less than to flying itself. He is a fighter no less than a flier. Thus far we know that while a good horseman or canoeist makes a good aviator, a good aviator makes a poor sailor. The preferred age period is 18 to 30 years. Under 18 the judgment is bad while over 30 one begins to tire more readily. The aviator must not be too short—not under five feet one inch. He must have a firm abdominal wall, without weakness or threatened hernia, for changes in intraabdominal tension predispose to fainting attacks. Men who have suffered injuries in other services may sometimes have the qualifications of an aviator, but those who have been struck in the head are not dependable. It is the man disabled in one or both of his lower limbs and hence not available for marching who can often be made into a flier.

The French warn against abuse of alcohol and tobacco by fliers but do not forbid mild indulgence when off duty, and one English student of flying (Graham Anderson) sees nothing to be gained by teetotalism. The policy of abstinence imposed upon American fliers will have a chance to demonstrate its superiority, if it possesses it. Untreated and uncured syphilitics are undesirables. Malarial subjects are excluded although Anderson believes some can be utilized by keeping them under quinine control. An abdominal band is worn if there is a relaxed wall. When a height of 16,000 to 18,000 feet is to be negotiated a respiratory apparatus must be present in the plane for no one can foresee what may happen on a given occasion. Good natural vision is a prerequisite for one must not depend on glasses because of their perishability. However, one cannot be too absolute in this respect and there are some excellent pilots who depend on glasses. Men with bent septums have been found to have severe headaches on landing. Mouth-breathers are subject to sore throat and deaf subjects and those with running ears cannot be used as pilots. An aviator should have a good sense of equilibrium and good muscle sense when the eyes are bandaged, for eye control is impossible in fogs. The labyrinth tests are useful in selecting candidates. Reaction time should come up to certain standards and tests of powers of observation are also made.

A Case of Ratbite Fever.—Complete case reports of this affection are rare. The earliest French victims of the disease were civilians and ratbite fever, or sodoku, has never loomed up as a military malady despite the plague of rats in the trenches. In the *Journal de Médecine de Bordeaux* for April, Mauriac reports a case in an artilleryman in great detail. He was twenty-two years old and of previous good health until attacked by polyarticular rheumatism which kept him in bed thirty-five days. From this he made a good recovery. On August 3, at night, a rat bit him as he was about to take a piece of bread from his bag. The injury, a severe one, was on the index finger opposite the second joint. It was at once dressed and healed regularly. Toward the eighth day a red areola appeared with a general reaction. There were joint pains aggravated by motion. These were followed by an eruption on the limbs. There were loss of appetite and lassitude. The infection about the wound disappeared and creatization was not interrupted. The patient did not come before the author until August 18, when he entered the hospital. He was seen to be very pale and emaciated and of senile aspect. He complained of weakness, loss of appetite, and joint pains. The scar on the finger was normal, and there was no marked regional adenopathy. The joints exhibited neither effusion nor dryness. The discrete, red maculopapules, which were undergoing involution on the limbs, showed nothing characteristic. They were most marked on the forearms and legs and were free from itching. The viscera and the functions presented nothing abnormal. The temperature was mostly normal. The syndrome of asthenia and low blood pressure seemed to point to the adrenals and Sergent's white line was present. On August 24 there was a new outbreak of eruption on the hands and alæ nasi. On the 28th the fourth metacarpophalangeal joint of the right hand showed redness and swelling. A few days later more cutaneous lesions about the knees. On this occasion they were notably large. Other joints presented reactions but the phenomena were always short lived. At the time of new manifestations there was a subfebrile rise of temperature. Toward October 1 the disease appeared to have run its course. The treatment had consisted of aspirin, adrenalin, strychnine, arsenicals, and iodine tincture internally. On October 5 a positive Wassermann was obtained despite denial of syphilis and absence of all evidence. He then received four injections of novarsenobenzol at a time when his symptoms had nearly vanished. The Wassermann remained positive, however.

In commenting on the case the author calls attention to the absence of fever (the disease has been termed ratbite fever). However, this could easily have run its course by the time the patient had come

under control. But there should also have been a sharp febrile attack with each new outbreak of symptoms, instead of a mere subfebrile increase. Myalgias were also absent in the author's case. The arthralgias and eruptions seemed typical enough. According to Martmotti, sodoku is characterized by a triad of salient symptoms—exanthem, intermittent fever, and myalgias; so that the author's case must be regarded as strongly atypical. Anemia was marked at first, and six weeks after the bite the red cells counted 2,640,000. This condition, however, soon improved. Nothing was found in the blood by hemoculture and animal inoculation of blood was negative.

Did this man have syphilis or is sodoku so closely allied to it as to give the same reaction? We know that in a way the Wassermann is a reaction for a group rather than for one disease. Or could the exanthem and arthralgias, the profound anemia, etc., have been due to cryptogenic syphilis? The Japanese have described atypical sodoku with presentation of symptoms much like those of the author's patient.

Prevention of Sickness in the British Army.—In a general sense the British Expeditionary Force in France is the healthiest community in the world. It is mainly composed of young men of selected physique who are well fed and well clothed, and who lead a healthy life in the open air under such conditions as are possible; there is limitation to this "possible" imposed by military necessities, such as overcrowding in huts, tents, barns, cellars, dug-outs, and billets, and the exhausting effects of exposure to bad weather, want of sleep, and neglect of personal cleanliness during prolonged tours of duty in the trenches. These unavoidable and irremediable exceptions to healthy conditions are quite sufficient to justify a recurrence of those diseases which destroyed armies in the past, but the long hoped for impossible, the miraculous, the inconceivable has materialized; the scientists have triumphed, and typhoid fever and dysentery which previously decimated armies in every part of the world, have been eliminated. Typhoid fever is now a negligible factor, and dysentery occurs only under exceptional circumstances. The most successful generals in the great war are those generals of science who have won such decisive victory over the ubiquitous and elusive typhoid bacillus; it has been an uphill struggle of twenty years' duration, marked by adversity, opposition, and accident, but inoculation has at last been universally accepted as essential for the purpose of the war. As an aid in the prevention of typhoid fever the search for and segregation of carriers has doubtless played a part. The experiments for ridding carriers of their germs have not been successful. Carriers are not allowed to return to the army but they are taught how not to be a danger to the community and are sent to their homes. Dysentery has not lived up to its historical reputation. The troops are well fed on the army ration, supplemented by fresh vegetables and other extras purchased locally and the water they drink is that drunk by the inhabitants, made doubly safe by sterilization. Consequently their resistance to this disease is high. There was, however, a local outbreak connected with one of the British advances into a devastated area, studded with shell craters and pits, full of fouled water, which proved too tempting for thirty troopers; the outbreak entirely disappeared from the area on the restoration of a pure water supply. The local type of the disease is bacillary but sporadic cases of the amebic variety introduced by troops from India and the Mediterranean crop up from time to time. The spread of the disease is controlled by mobile bacteriological laboratories which examine every suspected case, and by the segregation of carriers until they are germ-free. A prophylactic vaccine has also been prepared, ready to meet any further requirements. The prevailing diseases in this war are fortunately of a much simpler and milder type. The commonest diseases are trench fever, boils, and scabies. Trench fever is accountable for about one per thousand of strength, skin diseases, boils, and scabies for about one per thousand, and a varied assortment of ailments, such as bronchial catarrh, sore throat, digestive complaints, myalgia, dental trouble, hernia, and sporadic cases of infectious disease for the remaining half per thousand of strength.

Trench fever is a new disease peculiar to this war. Two clinical types of the disease are distinguished, the one a short fever of a few days' duration followed in four or five days by a single relapse and the other a longer illness characterized by the number, sharpness, and periodicity of the relapses. Headache behind the eyes and trench shin are the only constant symptoms. Reliable statistics prove that the disease is contracted in equal numbers by those in the trenches and those in rest billets near the trenches; very few cases originate behind the fighting area. The louse is under strong suspicion as an intermediary, but cases occur as far back as Corps Headquarters, under circumstances which seem to preclude that origin; there may, however, be more than one mode of dessemination. Trench foot is capable of destroying an army in a very short time. Preventive measures are equally sure of saving an army. The remedy to the unimaginative presents no difficulties, it is simply the maintenance of dry feet; but in practice it involves one of the most intricate problems in organization connected with the war. During the trench foot season—autumn, winter, and early spring—before starting on his tour of duty in the trenches each soldier has his feet washed and rubbed until they are warm, then whale oil or some other grease is well rubbed into them. This application helps to keep the feet warm. The next duty is to put on dry socks and to receive a spare pair, sometimes two pairs, for future use. Rubber boots are better for wet trenches and leather for dry ones, irrespective of temperature. The air spaces in leather boots are non-conductors and conserve heat, they also allow a useful amount of transpiration. Rubber boots confine the perspiration, the feet and socks become sodden, especially after a long walk, and heat is gradually lost. A clean, dry pair of socks per man is delivered daily at the trenches by the ration party in exchange for a used pair; these are changed and the feet are rubbed and oiled in appointed dugouts in or near the firing line. Other

preventive measures are the provision of hot soup, cocoa, or tea during the night and arrangements for keeping every man exercised. The question of relief is also essential; it is not safe to keep men in cold, wet trenches for longer than four days, and in exceptional cases the tour is reduced to twenty-four hours.—*The Hospital.*

Low Death Rate From Disease in the Army.—According to a statement recently issued from the office of the Surgeon General, a health rate, which as far as known has never been surpassed, has been established by the American Armies both here and overseas. For the week ended July 26 the combined reports of the American Expeditionary Forces and of troops stationed in the United States show an annual death rate for disease of 1.9 per 1,000—less than 2 men per 1,000 per year. The annual death rate for disease of men of military age in civil life is 6.7 per 1,000. This new rate is based on an approximate strength of 2,500,000 men, and includes men living under abnormal conditions. The overseas record was made while American soldiers were participating in the heavy fighting in the Marne salient, when they were frequently compelled to sleep and eat under the most primitive conditions. That this record is truly representative of the general health of the troops is shown by the combined reports, which indicate the figure of 2.8 per 1,000 as the average death rate for disease during the past two months.

Chiropodists in the Army.—It is announced from the office of the Surgeon General that so far as is consistent with the military demands, chiropodists taken into the army will be transferred to the Medical Department and either assigned directly to the various camps for duty under the camp surgeon or first sent to Camp Greenleaf for further training under the regular orthopedic instructors. On the demonstration of proper skill and attainments they may be advanced to the grade of sergeant. A canvass of the camps is now being made to determine the need of this particular service.

Yale University Buys Hospital.—Yale University has purchased the Elm City Hospital, a private institution, and will take possession of the property on September 1. It is planned to use the newly acquired property for Government work in connection with the Yale Army Laboratory School and the medical side of the Chemical Warfare Service.

Lieutenant Sidney Lehman Spiegelberg, a volunteer in the Medical Reserve Corps of the United States Army, died recently in France. Further details regarding his death have not yet been received. He was a graduate of the College of Physicians and Surgeons, New York, in 1906, assistant genito-urinary surgeon to the Sea View Hospital, and surgeon to the German Dispensary.

Captain Paul Eugene Betowski, M. R. C., U. S. A., died July 2, from injuries received in an automobile accident, at the age of 37 years. He was a graduate of the Long Island College Hospital Medical School in 1907, and was, before entering the Medical Reserve Corps, surgeon to the Soldiers and Sailors Home at Bath, L. I. He was attached to the 666th Aero Squadron, A. E. F., France.

Athletes Rejected for Military Service.—The records of physical examinations of drafted men at Camp Dix, Wrightsville, N. J., show that in proportion to their representation among recruits professional athletes show more physical rejections than any other group of men called to the National Army at this camp. This paradoxical situation has been observed since the opening of the camp, and it is thought probable that other cantonments have had a similar experience. In a recent draft there were three famous ball players, a boxer, and a runner with a track championship, all of whom failed to qualify physically for military service.

Dr. Rudolph B. Teusler, in charge of St. Luke's Episcopal Hospital at Tokio, will lead the American Red Cross Unit which will accompany the American troops on their expedition into Siberia.

Red Cross Activities.—A report under date of August 25 shows that the American Red Cross has supplied 1,100,000 surgical dressings to the American wounded during the past month. Twelve hospitals are being operated near Paris, four new ones are being built, and convalescent homes have been established at Biarritz and other places. The American Red Cross is now operating farms for the convalescent aggregating 249 acres. The report dealing with supplies shows that each division of the Army receives 2,500 daily papers and 500 weeklies. Heavy demands will be made upon the American Red Cross in connection with the international campaign against the Germans, Austrians, and Bolsheviki in Eastern Siberia and steps have been made to meet these needs. At the request of the General Dietrichs, commander of the Czechoslovacs, the Red Cross has already begun the equipment of a base hospital at Harbin containing from 300 to 400 beds. A hospital train is expected at Vladivostok soon, where 240 Czech patients are now being cared for in the fortress hospital.

New York Hospitals Confer With Surgeon-General.—The Hospital Conference of New York City, at a meeting on August 26, voted to send a committee to Washington to confer with the Surgeon-General for the purpose of forming a definite plan to furnish the greatest amount of medical aid and nursing aid to the Army without entirely disorganizing the civil hospitals. This meeting was called after a number of the hospitals of New York City had received word from the Surgeon-General's office that plans had been developed for calling out hospital internes and a certain number of advanced and intermediate medical students. In a statement issued on the situation, the Hospital Conference of the City of New York appeals to the President of the United States to direct the War Industries Board, the Provost Marshal General, and the Surgeon-General of the United States Army "to formulate in accordance with existing laws, regulations which, while giving due precedence to immediate military needs, will, nevertheless, preserve the integrity of the civil hospitals of the country as instruments of public service essential to the immediate care and comfort of the civil population and necessary to the conduct of the war, in relation to which the hospitals serve as training schools for medical officers and nurses."

MEDICAL RECORD.

A Weekly Journal of Medicine and Surgery.

THE SYMPTOMATOLOGY OF PAINFUL DYSPNEA.

THE symptoms of painful dyspnea are not of equal value, and although some are found in each case history, with variations which do not alter the general outline of the syndrome, others appear to occupy a more modest place. The cardinal symptoms are three in number, namely: venous symptoms, pain, and dyspnea, the union of which forms the basis upon which the diagnosis rests. From the clinical standpoint and pathogenesis, the venous manifestations are the most important. They are always met with, and are the first to appear, and confer the individuality upon painful dyspnea and testify in a tangible and visible manner to a dilatation of the right heart which plays the most important part in the mechanism of the accidents.

Usually, an obstruction to the venous circulation is made manifest by a more or less evident cyanosis of the face, lips, and limbs. Shortly after, the paroxysm still persisting, the liver will be found to offer a marked and progressive hypertrophy. To these symptoms edema of the legs becomes added, and this can be explained only by a slowing down of the venous flow, because in most cases it arises only during the paroxysm and quickly disappears when the former has subsided. It is also possible that nephritis, when present, may have some influence on this interior heart edema. The venous symptoms remain as long as the paroxysm of painful dyspnea, and cease with it, showing their intimate relations to the other elements of the syndrome. The right heart will always be found dilated, due to pulmonary hypertension, which governs in turn the intensity of the venous symptoms. On the other hand, the anatomical and functional states of the left heart never undergo morbid change, while the aorta is free from any lesion.

The painful phenomena recall those of true angina pectoris, but particularly those of the pseudo variety. The pain, which is tearing and constrictive, has its maximum intensity in the retrosternal or precordial region, and, as in angina pectoris, it extends to the back and arms, especially the left.

While the venous and painful symptoms are well defined, the same cannot be said of the dyspnea, which borrows its characters from the causative factor of the syndrome. Since it is due to the dilatation of the right heart and pulmonary hypertension, it may vary in type, when the paroxysm has been caused by bronchitis in an emphysematous subject, by an attack of asthma or by some obscure reflex cause. In some cases albuminuria is noted at the end of the paroxysm, but it soon disappears. This succession of phenomena would seem to show a relation of cause and effect between the elimination of albumin and the paroxysm of painful dyspnea.

The paroxysms of painful dyspnea usually are nocturnal, and may follow a physical or intellectual effort, but generally no particular cause can be made out. The cyanosis suddenly appears, rapidly involving the face and limbs. A severe precordial or retrosternal pain is felt, the patient is restless and oppressed, but perfect control of speech is retained. The right heart is dilated from the pulmonary hypertension, and contrasts with the left heart, which is normal. The radial tension is not increased, the sphygmometer registering from 150 to 180 mm. Hg. At the same time, the liver may be found enlarged, with edema of the lower limbs. The paroxysm lasts several hours or days, and when it ceases the distension of the right heart disappears at the same time as the circulatory, nervous, and dyspneic disturbances. Related to the affection which has caused them, the paroxysms recur just so long as their causative factor exists, and disappear definitely with it. Therefore, it is impossible to formulate an individual prognosis of painful dyspnea considered from the standpoint of its ultimate evolution, but the immediate prognosis is good.

AN ITALIAN VIEW OF ANGLO-SAXON MEDICAL JOURNALISM.

DR. VERNEY writes a long essay on this subject in *Il Policlinico* for June 23. Before the war the Italian physicians knew too little of this literature, for they were inclined to regard German journals as the last word in medical advance. They have now learned better, and to give his readers an idea of Anglo-Saxon journalism the author analyzes two journals each among British and American periodicals, namely, for the former the *British Medical Journal* and *Lancet*, and for the latter the *Journal of the American Medical Association* and the MEDICAL RECORD. The first named under each head is the official organ of the national medical association. In scope these four journals are of the omnibus type, and take cognizance of every kind of professional activity. The circulation of the two official organs is enormous because of certain privileges. Both of the British journals publish special foreign editions.

The original articles come first in these periodicals. These are made up of lectures and addresses and papers read before medical societies. The latter predominate in the two American journals, and the vast number of societies and congresses in the United States assures plenty of material. The sub-

jects are practical rather than speculative, and of general rather than special interest. Case histories are common. The author thinks the preponderance of these subjects makes the reading a little dry. The synthetic reviews so common in European journals are not often encountered. The American journals, however, show an extreme variety of topics, with occasional reference to the novel and speculative, and the author cites with approval the articles in the MEDICAL RECORD by the late Dr. Maverick on the "Mistakes of Nature," as penetrating, limpid, and original, and as exemplifying the type of articles welcomed in American journals. In passing, he mentions the numerous articles on new instruments and apparatus as characteristic of the Anglo-Saxon genius.

But the editorials are in reality the most important articles, and the part played by them is the greatest point of difference between Anglo-Saxon and European journals, for the latter usually eliminate this feature outright. The editorial is what is read first, and perhaps all that receives attention. It comprises the leading articles and the annotations. The author regards the custom as a capital one, for it gives in a small compass the current topics of the day in which the progressive physician should be most interested. The third feature is the Correspondence, which may, of course, be carried to a great extent, including not only the communications of the regular staff correspondents in distant countries, but letters on all conceivable subjects from miscellaneous readers. Often these communications are of singular interest and importance.

The fourth rubric is that devoted to Social Medicine in the widest sense of the word—the relations of practitioners to one another and to the general public. The so-called educational numbers published annually belong under this head.

The fifth rubric comprises both Book Reviews proper and reviews of periodical literature. All four journals are active in this field, and the writer notes incidentally that the MEDICAL RECORD covers some of the Italian medical journals, as *Il Policlinico*, *La Riforma Medica*, and the *Annali d'Igiene*. The writer states that the German abstracts were originally suppressed at the outbreak of our war, but adds that they were afterward resumed by the MEDICAL RECORD. He applauds this course, for there is no reason, he states, why we should not learn from our enemies. The Anglo-Saxon journals are strictly impartial and catholic in their selection of literature.

Under the head of miscellaneous rubrics the author shows interest in the MEDICAL RECORD's examination questions and answers. Dr. Verney will devote a second paper to some of the special periodicals of the Anglo-Saxon medical world.

MEDICAL MOBILIZATION AND MEDICAL STUDENTS.

IT has been proposed that the medical profession of the country should be mobilized. This will be a long step in the right direction, for many more medical men will be required for army needs than have yet entered the service. It is, however, not only with the view of selecting or gaining information as to the most fitting ones for this service that the profession should be organized, but in order to be in the position to apportion, or suggest, to each man the medical duties for which he is best adapted. A fairly large proportion of the medical men of this country, for good reasons, cannot serve in the army, but by being properly organized they will be enabled to perform civilian services to the best advantage from the point of view of the community at large and of the military situation in particular. To each practitioner will be allotted the task which promises to be of the greatest benefit to the country as a whole. Undoubtedly, sacrifices will be called for, but when the stake at issue is taken into consideration such sacrifices should count as nothing. Moreover, judicious mobilization of the profession will make a fair disposition of its individual members possible, and greatly reduce the possibilities of abuse of opportunities brought about by the war.

The proportion of medical men to the population is much greater in this country than in Europe. In Great Britain, for instance, there are about 28,000 qualified practitioners to a population of 45,000,000, and from this number had to be taken sufficient to serve an army of 6,000,000 or so and a navy of more than 300,000. In America, with a population of 100,000,000, there are in the neighborhood of 140,000 medical men, and, as a matter of fact, at the present time there are in the American army more surgeons than in the entire British army and navy. Conditions in this country as regards the supply of available medical men are far more favorable than in the European countries at war, and if mobilization of the profession is carried out wisely there is every reason to believe that the army and navy will be adequately provided with medical service, and that there will still be enough medical men left to care for the health of the civilian population.

It will not be necessary in America to call upon medical students to serve in the army or navy. In Great Britain this has been done for some time, and the destroyers, as a rule, have fourth and fifth-year medical students, known as surgeon probationers, acting in the capacity of all-round naval medical men. There has been some confusion in Great Britain recently as to the manner in which the War Department makes use of medical students, and Professor Bryce of Glasgow has published the facts in the *Glasgow Medical Journal* for June, 1918. These, in brief, are as follows: No man who has been graduated in medicine within the past four years has entered civil life unless he suffered from some serious physical disability. On the day of his graduation every man has passed automatically into the service, either on sea or on land. Any release of men on service to continue their studies, or any exemption of men actively engaged in their studies, has been dictated by the public interest solely, the immediate object being to recruit the ranks of the medical service of the navy or army.

This being so, the principle that has ruled has been the release or exemption of the men who could in the shortest time become available for the medical services of the navy and army. As the war went on, and the fourth and fifth-year men were all drafted, it became necessary owing to the depletion of the third-year men by some 80 or 90 per cent., to release third-year men already in service, and recently it has been found necessary to extend this to second-year men. Students who had actually become second-year students by passing their first professional examination, or who could pass this examination by July 31, 1918, were temporarily exempted in order that they might complete their second examination at the first opportunity, and then take service as surgeon probationers in the navy. This applied only to men who entered on their studies not later than October, 1917. No others could fulfill the conditions.

All men of military age who are temporarily exempted under the instruction are required to combine military training with their professional studies in order that they may be ready for service when called upon at the appropriate stage in their curriculum.

It will be gathered from a perusal of the above that virtually all students are liable to military service, if they have not proceeded far enough with their studies to render their medical services of probable value in the war.

Pituitary Extract in Obstetrics.

The introduction of preparations of the pituitary body into the practice of obstetrics has practically revolutionized this branch of the medical art. But unless the indications for its use are strictly adhered to, it can do much harm, and in consequence unjustifiably fall into disrepute. By its use, difficult labor from failure of the uterus to contract is practically overcome. It is essentially a reenforcer of contractions. In multigravidae its effect in this respect is sometimes almost miraculous; in primigravidae it is less remarkable, but the drug is still successful in over 50 per cent of the cases where the fault is distocia uteri. But the use of pituitary extract must be confined to actual labor, for at other times it is valueless. It is a question whether it is of any service in bringing on labor at term, because it is difficult to determine this time to the day, and if given at any time before term, no matter how short, it is of no avail. Its action is that of an internal secretion. Labor at term being a sort of magnified menstruation, is brought about through the influence of the secretion of the posterior lobe of the hypophysis. During pregnancy there is a sort of inhibition against its action, which inhibition is probably exercised by an internal secretion given off by the placenta. It is not known what it is that removes the inhibitory action of the placenta, but in all likelihood it is a secretion from the decidua and the uterus. When the placental inhibition to the action of the hypophysis is removed labor begins; the secretion of the gland then stimulates the contractile action of the uterus, and it is the province of pituitrin to reenforce this action. But if there is some obstruction to labor it is neither desirable that the usual labor contractions go on until the obstruction is removed, nor of course that these undesirable contractions be reenforced artificially. It is, therefore, a rule that allows of no exceptions that pituitary extract must not be used unless the head is engaged in and through the brim of the pelvis. When it is given in small doses, 2 to 5 minims every half hour, it intensifies uterine contractions and shortens labor. Chloroform, however, seems to inhibit its action, but if the patient is not completely under and is given the pituitrin the expulsion may be so precipitate as to cause severe lacerations. While it is a rule that pituitrin must not be given before labor or before the engagement of the head through the brim, it must likewise not be given in the third stage of labor, for while it produces marked contractions, the equally marked periods of relaxations may cause severe hemorrhages. In any event, the drug is a powerful one, and must not be administered unless the medical attendant can remain constantly in attendance, both because of the tendency to rapid delivery and the consequent possibility of laceration, and because of the danger of subsequent hemorrhage.

Strychnine in Neurasthenia and Anxiety Neuroses.

The use of heroic doses of nux vomica and strychnine in nervous collapse is well enough known to neurologists, and recently Heckel in a monograph on neuroses of anxiety has recommended the alkaloid in those states as well. Hartenberg regards strychnine as almost a specific in the nervous asthenia of neurasthenia and gives it in increasing doses—always in excess of 6 milligrams (1/10 grain) daily dose. By reason of the fact that strychnine is not retained in the body certain individuals can acquire a tolerance of several centigrams a day. In anxious states this high dosage is not indicated and by the mouth a tenth of a grain daily dose need not be exceeded, while a fifteenth suffices by the hypodermic route. To give larger doses would very likely increase the severity of the anxious state. The remedy is indicated, according to Hartenberg, in secondary neurasthenia due to organic disease and wherever there is a somatic substratum. In endogenous cases with obsessions and phobias the results are less happy. When the drug is given *per os* it exerts an action on the digestive apparatus as shown by acceleration of the food passage. Given subcutaneously a nervous reaction soon follows and if this is in excess the patient is irritable and restless. To strike the ideal dose it is well to begin with a milligram by the mouth. On the ninth day Hartenberg would change to 2 milligrams in two daily doses, one on waking in the morning and the other during the day. One may or may not increase the dose further, but 3 mg. daily should not be exceeded. After three periods of treatment the patient should rest a fortnight, after which the treatment is begun again with daily doses of 2 mg., which may be gradually increased until benefit arrives or the limit is reached. If the digestive organs demand it the alkaloid should be given *per os* in pill form.

News of the Week.

The Value of School Lunches.—The following statement was issued by the Public Health Committee of the N. Y. Academy of Medicine, on August 8, 1918: Malnutrition among our children is much more widespread than people as a rule realize. It is a condition found in a considerable proportion of the children. In New York, the premier city of America, at least 10 per cent. of the children suffer from some degree of under-nourishment. Ignorance of food values is one of the several major causes of this phenomenon which, if unchecked, will cause a serious impairment of our vital resources. Since the war the importance of the problem has become palpably intensified. The necessity for food conservation and the scarcity of some customary foods and the high prices have combined to focus our attention on the problem of nutrition as never before. Changes in strongly intrenched habits cannot be wrought precipitately. Even when mothers have learned how to adapt the menu to scientific dictates and to conditions indicated by our conservation policy, their efforts fail unless the children learn to like the food placed before them. It has been proved by demonstration in this city and elsewhere that in groups children will much more readily eat food to which they have not been accustomed. Peculiarities of taste and racial customs are readily overcome through the stimulation of group feeding, the children eating the new foods with relish. In this wise they develop habits for wholesome and nutritious foods, which they have not been receiving at home. They take back into the homes the taste for the new foods and by the thus stimulated demand improve the home dietary. Herein lies the educational value of the so-called "school lunches" which in many cities of our country and in other countries have proved to be of genuine benefit to the children in a great variety of ways. School feeding, on a self-supporting basis, should be made a part and parcel of our educational system. Hitherto a committee of private citizens have maintained the "school lunch" in a number of schools, but the existing urgent demand for the extension of this service makes it imperative for the city to assume control over it and extend it in accordance with the well-recognized needs. The cost involved in the municipalization of the school canteens is so insignificant in comparison with the total budget of the Department of Education that it should not deter our city government from instituting this important service at the opening of the new school year in September.

The Baltimore Quarantine Station, which was finally taken under the control of the Federal Government the latter part of May, has been placed under the direction of Dr. J. A. Nydegger, surgeon of the U. S. Public Health Service. New York is still under State control, although the officer in charge, Dr. Cofer, is in the Public Health Service.

Disease on Incoming Steamships Not Influenza.—As the result of an investigation made by the New York Health Department, Commissioner Copeland announces that the patients taken from incoming steamships recently, supposed to be suffering from influenza, did not have the disease. Eleven patients taken from one vessel had penumonia or bronchial trouble, but no germs of influenza were found.

Fire in Brooklyn Hospital.—A fire occurred in St. Mary's Hospital, Brooklyn, on the morning of August 23 which caused $5,000 damage. The Sister Superior had the shades of all windows facing the blaze drawn so that patients could not see the flames and handled the entire situation so skilfully that none of the two hundred patients was disturbed.

Hospital Aid for Aisne Civilians.—A report received by the American Committee for Devastated France announces that hospitals for the care of civilians have been established in the Aisne disthict by the American Woman's Hospitals.

Anniversary of the Bureau of Child Hygiene.—The personnel of the Bureau of Child Hygiene of the New York Department of Health celebrated its tenth anniversary on August 19. Health Commissioner Copeland called attention to the fact that this was the first bureau of its kind in the world and that it had set a standard in the conservation of child life and health. In 1907, a year before the founding of the bureau, the baby death rate for Greater New York was 144 per thousand births; in 1917 there were 88 deaths out of every 1,000 babies born, and up to date this year the average mortality has been 85 per thousand. It is not reported that Mayor Hylan was present.

Gifts aand Bequests.—The Lyons Home for Crippled Children and the Davis Industrial School for Crippled Children, New York, receive each $2,500 and the Homeopathic Hospital $5,000, under the will of Alphonse Galôt.

By the will of Ethelaide Bump the Corning Hospital, Corning, N. Y., receives the principal of a trust fund amounting to several hundred thousand dollars on the death of a beneficiary.

Obituary Notes.—Dr. Louis H. A. Schneider, a graduate of the College of Physicians and Surgeons, New York, in 1890, died at his home in New York, August 22, aged 49 years.

Dr. Jacob H. Gallinger of Concord, N. H., died of cardiovascular disease on August 17. He was born at Cornwall, Ontario, March 28, 1837, and was graduated from the Medical Institute, Cincinnati, in 1858, and from the New York Homeopathic Medical College in 1868. He practised medicine in Concord from 1862 to 1885 and was surgeon general of the State in 1879-1880. He served a number of terms as representative and as senator in the State legislature, and since 1891 had been a U. S. senator.

Dr. Arthur D. Dryfoos, formerly a captain in the Medical Reserves of the United States Army, died suddenly at his home in New York City on August 22. He was a graduate of the College of Physicians and Surgeons, New York, in 1899, a member of the New York Academy of Medicine and the Neurological Society, assistant neurologist to the Lebanon and Vanderbilt Clinics, and attending neurologist to the German Dispensary.

Dr. John H. Landis, a graduate of the Medical College of Ohio in 1890, died at his home in Cincinnati on August 22, aged 58 years. He was an international authority on public health and medico-legal questions.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE DEVELOPMENT OF MEDICAL EDUCATION—DEATH OF TWO DISTINGUISHED CONSULTANTS—HYSTERIA IN SOLDIERS.

London, August 2, 1918.

A MEMORANDUM has been addressed to the president of the Board of Education, Mr. H. A. L. Fisher, by Sir George Newman, chief medical officer and principal assistant secretary to the board, dealing with the present position of medical education in England, and making many suggestions for its reform in practical directions. The origin of the memorandum is the strictly business position epitomized in the proverb that "he who pays the piper should call the tune." Just ten years ago an application was made by the medical school attached to St. Mary's Hospital in London to have that school recognized as eligible for a grant from the Board of Education as a regular technical school. The British medical profession has been, ever since it became an educated profession, accustomed to paying for its own training, to supporting its own professors by the fees of its pupils, and its own examiners by the fees of the examinees, so that the application came as something of a shock to the medical mind, while officialdom contemplated the request with deep distrust. The Board of Education, however, was an enlightened board at the time, while events were happening in every department of life to prove that a high standard of medical education, which could alone secure to the country a thoroughly competent medical service, was a public asset for the obtaining of which public money might well be expended. In the end the application of the St. Mary's School was favorably received, when applications quickly followed for the recognition of other medical schools in similar substantial manner, both in London and the provinces. But before recognizing a medical school as eligible for a grant the Board of Education had to be satisfied as to the nature of the arrangements, the government and management of each school, the permanency of its work, and the directions in which the allocated grant would be employed. This necessitated a system of periodical inspection by the board, and for this purpose the board associated with Sir George Newman Sir Clifford Allbutt, regius professor of medicine at Cambridge, and Sir Thomas Barlow, a late president of the Royal College of Physicians and consulting physician to University College Hospital. Sir George Newman's memorandum sets out the conditions under which medical schools have been recognized for these government grants, and the principles on which the grants are made. That the scope and the necessity of the grants may be understood, he deals in great detail with the present position and needs of medical education in England, with the character of our university training in medicine, and with the educational course laid down by the various universities and corporations through which the medical student can obtain admission to the roll of the profession. The memorandum, which is issued from His Majesty's Stationery Office at the modest price of 9d., is thus a compendious history of medical education in England to-day, coupled with running criticisms on its merits and defaults; and it concludes with recommendations for many particular reforms. These last may be summarized as follows

1. Unnecessary and redundant burdens should be eliminated from the medical curriculum proper by (a) relegating the study of the preliminary sciences (chemistry, physics and biology) to school life, and (b) reserving of work along special lines until a postgraduate epoch.

2. A more thorough linking up of the study of the intermediate subjects with the study of the clinical subjects, so that lessons learned while acquiring the science of physiology can be applied directly to the science of perverted physiology or pathology.

3. Large reorganization in the machinery of education in clinical medicine and surgery such as the provision of modern equipment, of adequate clinical and pathological laboratories and radiographic and electrical appliances, and of annexes for instruction in various remedial procedures, such as massage and hydrotherapy.

The memorandum may be of the greatest educational importance if its message is well received. Many of the medical education centers of this country are very well found. Some are very ill found. And the energies of the traveling committee of inspection instituted by the Board of Education must find full scope in the attempt to bring the less advanced schools up to the best standards. And this will mean the expenditure of much money, so that it is of good omen that the board should be willing to collect evidence, for a willingness, if satisfied of the necessity, to make further and substantial grants is thereby implied.

Death has removed this week two consultant physicians of widely differing age and equipment, but having this in common: that their careers were distinguished, and that they owed their distinction entirely to their devotion to the medical profession. Dr. Frederick Roberts, consulting physician at University College Hospital, was 79 years of age at the time of his death, and had retired from active practice for 15 years; while Dr. Frederick Batten, physician to the National Hospital for Paralysis, and the Great Ormond Street Children's Hospital, was but 52 years of age, and at the top point of his energetic career. Each lived for medicine. Professor Roberts, a Liverpudlian, was a triple gold medallist at the University of London, and after a short sojourn at Liverpool, as physician to one of his native institutions, returned to London, to be immediately appointed physician to University College Hospital, and the Brompton Hospital for Diseases of the Chest. At each center he made his mark as clinician and instructor. At Brompton his exhaustive methods of diagnosis were imitated by many generations of his house physicians; and at University College he was speedily elected professor of clinical medicine. But he will be best remembered by the textbook on medicine, "A Hand Book of Theory and Practice," which was the result of his garnered experience, and which was used as an examination manual by countless students during its nine editions.

Dr. Batten, the son of a distinguished London lawyer, was a Cambridge and St. Bartholomew's

student, who, after being casualty physician at St. Bartholomew's, specialized in neurology and pediatrics, and achieved while quite young a commanding position in both sections of his art. He was a really scientific and learned man, so that his diagnoses were trustworthy, but he was also a persevering and ingenious therapeutist, and the originator of many practical devices for rendering the treatment of paralyzed patients of all ages more tolerable and rapid. He was also an untiring worker in general professional interests and an honorary officer in many medical societies. The ranks of modern medicine can ill spare this devoted member, who succumbed suddenly to hemorrhage after an operation.

It is becoming abundantly clear that the separation of hysterical from organic conditions among soldiers is one of the most difficult problems which the medical profession will have to face, and they are already facing it with energy. From the very beginning of the war it was recognized that purely hysterical cases, if taken in hand early, yielded quickly and completely to treatment along many lines, and, somewhat to the disgust of the more materialistic school of therapeutists, two of the most useful agents for bringing about this happy result were discovered to be hypnosis and psychoanalysis. General anesthesia, carried to a certain point, was also useful in many cases, while electricity and reeducation along the indicated lines bore good fruit. Especially has reeducation been found to give extraordinary good results, illustrations of which are detailed in an interesting paper by Major A. F. Hurst, neurologist to Guy's Hospital, and Capt. J. L. N. Symns, neurologist to the Royal Victoria Hospital, Netley, in the columns of the *Lancet*. The experience of these specialists in the rapid cure of hysterical symptoms in soldiers is most encouraging, inasmuch as they are able to state that they are distinctly disappointed if, in many cases, complete recovery does not occur within twenty-four hours of commencing treatment, and this even where the patients have been in other hospitals for over a year. It is true that if a man with severe hysterical paraplegia of some months' duration is taught to walk in half an hour, and treatment is then discontinued on account of his fatigue, he will probably not walk normally until he has undergone reeducation for several weeks; but, continue the authors, "if the officer in charge not only ignores the patient's fatigue, but also his own, and continues the treatment for another half hour or hour, or even for two or three hours, the patient will end by walking with a normal gait, although, of course, some time will elapse before he completely regains his strength. In the same way, a mute or aphonic soldier who stammers on recovering his voice should not be left until the stammer is also cured, or he will only recover completely after receiving daily lessons for some weeks."

Major Hurst and Captain Symns rely upon simple percussion or reeducation, continued with manipulation, rather than upon hypnosis, where they find the results capricious; but they attach great importance to the creation of a proper atmosphere. A hopeful patient is for them a half-cured patient, while experience shows that if a cure is obtained within three or four weeks of the onset of symptoms relapse is very rare. The illustrative cases on which these optimistic conclusions are based are very interesting. Patients who had suffered from such conditions as paraplegia for eight months' duration, from talipes, tremors, and stammer, of 14 months' duration, from hysterical gait and tics of six months' duration, from hysterical paraplegia mistaken during three months for sclerosis, and from tremors of jaw and limbs lasting sixteen months—in these, and in other cases every whit as serious, sensational cure followed manipulation and suggestion in a few hours, occasionally in a few minutes. Of course, the weak spot in this cheerful record is the fact that the hysterical nature of many cases cannot be early recognized. Rapid recovery may follow the recognition of the true nature of the condition, but much time will often be wasted by the detention in bed of hysterical subjects who are supposed on very good grounds to be suffering from the organic results of shell shock or spinal concussion. Therefore, the more cases of cure that are accurately reported the greater will be the number of cures in the future.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

LIBRARIES FOR THE ARMY—THE NEGRO IN THE ARMY —ARMY BASE HOSPITAL NO. 6.

PARIS, July 16, 1918.

THE American Library Association has arrived in France with loads of books for Uncle Sam's fighting men on land and sea. Good, breezy, Western fiction, tons of it, and lots of reference books, dictionaries, histories, books of science, etc., straight from home and in sectional bookcases. Dr. M. Llewellyn Raney, librarian of the Johns Hopkins University in Baltimore, Md., and director of the Overseas War Service of the American Library Association, is the bearer of this good news. One hundred and ten cases have reached Paris, while hundreds of others are in the ports.

Dr. Raney was sent to Europe to map out the Association's procedure overseas. After study of British and French methods and extensive observations afield and at sea he presented to General Pershing and Admiral Sims a plan of operation. This they have not only approved, but have given practical aid to effect. At their request the tonnage necessary has been granted by Washington. The Quartermaster's Department is to erect a warehouse at an important interior point for the receipt of this material. Admiral Wilson has granted the use of a coast vessel for the distribution of books to naval aviation stations. The heart of the plan is the cooperation effected between the American Library Association on the one hand and the Y. M. C. A., Red Cross, Knights of Columbus, and Salvation Army on the other. These organizations, having already established contact with the men, are to be the chief distributing agencies. The A. L. A. thus becomes virtually the American base of books supply.

The service of the A. L. A. will in no way interfere with the technical work of the cooperating associations, such as their religious, educational, and medical service, any more than the public library in America disturbs the operations of the

church or school. The aim of the A. L. A. is to supplement, not to supplant.

A strong khaki-colored box, with screwed-on top, and a central shelf form the unit of shipment. Stacked, these constitute a neat sectional bookcase. The books are given out purely on the honor system, without deposit or fine, though a strict record of them is kept. "Play square with the other fellow, he has played square with you" is the motto adopted for the placard surmounting the shelves. Nor are the prisoners of war forgotten. Dr. Raney has been to Switzerland and effected an arrangement through the Y. M. C. A. for supplying these unfortunates with home consolation.

En route to America Dr. Raney expects to visit England again and effect final arrangements for service there. He left for home about the middle of May to cooperate from the home base. His place in Paris was taken by Burton E. Stevenson, the author, who with his wife has arrived at the Hotel de Crillon. Mr. Stevenson organized one of the most successful of the cantonment libraries in America, that at Camp Sherman, Chillicothe, Ohio. He is at present looking for A. L. A. headquarters. These quarters will constitute virtually an American reference library in Paris.

Strange as it may seem the American soldiers most susceptible to homesickness are the negroes from the South. One of them is a cook for a medical unit, and is probably the best cook outside of Mississippi. He can't, like the French chef, make a dish for a king out of bully beef, a blade of grass, and a bit of vinegar, but he can make a rice pudding such as France never saw. He can also serve hot-baked potatoes in a way which Americans thoroughly appreciate. Recently he was asked if he liked it in France. "Well, sah," he replied, "France is a fine place, I reckon. I say I reckon because I hain't seen much of it; but I understand, sah, that all that paht I hain't seen is pretty fine country, and once in a while they have sunshine there too. This mud we have round heah's a little different than the mud we have in Georgia and Mississippi, but there's one good thing about it, it never gets deep enough to drown in and that's where it differs from the Mississippi River." "Would you go back if you were released?" "Say, sah, I was foh years the chef on a diner between Birmingham and Atlanta and maybe that wasn't the best job in the world, but if I were told to go back, sah—well, you've heard of those homing pigeons." I told him I had. "Well, that's me, sah. I am a homing pigeon."

A former lyceum somewhere in France has been converted into an American hospital, technically known as Base Hospital No. 6. The situation is remarkably fine and does credit to the Medical Department of the United States Army, for the hospital is in the midst of green trees and pleasant views. It is worked out in all details with precision and a view to order. At the head of this beautiful hospital is Major Frederic A. Washburn, and the heads of departments are: Major Richard C. Cabot, chief of the medical division; Major Lincoln Davis, chief of the surgical division; Captain Roger Kinnicutt, pathologist; Captain James H. Means, adjutant; Captain William J. Mixter, registrar. This hospital is located in buildings the nucleus of which is the stone building of a boys' academy. The academy was taken over by the French army at the outbreak of the war and fourteen pavilion wards were erected outside it. Since this hospital was taken over by the Americans the adjoining large estate has been leased. This gives us a total of sixty acres for the hospital enclosure. Upon this land are being erected some sixty-six new buildings—wards, kitchens, quarters for men and nurses, recreation rooms, dining rooms, and warehouses. The hospital has a capacity of 2,000 beds authorized. It is now reporting 1,800 beds available.

The names of fifty officers are borne on the rolls; these include the medical officers, sanitary officers, quartermaster, chaplain, and dentists. Many of these officers are continually on detached service. At the present time there are two surgical teams at the front. There are 82 women nurses and 228 medical department soldiers. The hospital at the present time serves two functions—it cares for the more serious cases of sickness and accidents in the large rest camps at other posts in this base section, it cares for patients transferred from other base hospitals nearer the front, and also for cases directly from the front. Most of the officers of Base Hospital No. 6 are drawn from the Massachusetts General Hospital.

CANADIAN LETTER.

(From a Special Correspondent.)

INFANTILE MORTALITY AND TUBERCULOSIS IN THE PROVINCE OF QUEBEC—INFLUENZA IN MONTREAL—DEATH OF DR. LACHAPELLE—MEMBERS OF M'GILL MEDICAL FACULTY IN ACTIVE SERVICE—NEW DEAN OF THE MEDICAL FACULTY OF LAVAL UNIVERSITY—THE SALE OF SOOTHING SYRUP TO BE PROHIBITED IN TORONTO.

Montreal, Aug. 12, 1918.

Infantile mortality is high in Montreal, but the vigorous steps which are being taken by the Board of Health of this city are already having a good effect and undoubtedly in the course of time will bring down the death rate of infants to the level attained by many other cities. The sanitary conditions of some parts of Montreal are somewhat primitive and it is said that the French Canadian habitants of the poorer class have a prejudice against free ventilation of their houses. Also the women of this class are ignorant of the best methods of rearing infants and young children, and this lack of knowledge has had a good deal to do with the high death rate. However, "nous avons changé tout cela" or are in process of doing so. The Montreal Board of Health has inaugurated a system of visiting nurses who go into the houses of the poor and teach mothers how to feed babies properly and otherwise instruct them in the principles of domestic hygiene.

In the rural districts of Quebec, the state of affairs as regards household hygiene, the infant mortality rate, and the prevalence of tuberculosis is worse than in the cities. There are no visiting nurses to advise the mothers and the habitants are largely left to their own devices so far as rearing

their families and combating tuberculosis are concerned. This is not to say that the Provincial Board of Health is not efficient. Its members are doing excellent work, but the care of infants and children and means of effectually fighting tuberculosis are beyond their scope. The co-operation of the people themselves is essential for success in these spheres of endeavor.

It has been suggested by Dr. Elzear Pelletier among others, that the situation in the Province of Quebec is exceptionally favorable for the creation of a competent antituberculosis league or organization, more favorable, in fact, than in the English speaking provinces of Canada. In Quebec there are 891 Roman Catholic parishes of which no fewer than 390 possess communities of nuns. The suggestion then is, that the antituberculosis leagues should request these religious orders to take a more active part in questions of social hygiene. For example, almost half of the Catholic rural parishes have convents, and therefore half of the territory of the province could be covered by nuns trained as nurses who could carry an effective campaign against tuberculosis. It would seem, indeed, entirely feasible that the nuns could attend not only to their own parishes but also to all the provincial parishes. Neither need such beneficial work be restricted to fighting tuberculosis, but, as in the cities, these nuns could instruct mothers in domestic hygiene and especially in the most hygienic methods of bringing up children. Moreover, it would appear to be wholly within the powers of these nurses to inspect school children. That is to say, to tender advice as to children not up to the normal standard of health and when necessary to suggest that a physician be consulted. By proceeding along these lines, infant mortality would be greatly decreased, tuberculosis would be checked, and the health of the rural community would be immeasurably bettered.

There has been somewhat of a "scare" in Montreal with respect to what is termed "Spanish" influenza. Although no cases have been reported in the city, the fact that Montreal is constantly receiving soldiers returned from the war fronts, causes a certain amount of concern. A most common-sense view of the situation has been taken by Dr. Pelletier, who has given it as his opinion that the disease is just "grippe" and not a deadly new malady.

Dr. E. P. Lachapelle, the president of the Provincial Board of Health of Quebec since 1885, died on August 1, following an operation at St. Mary's Hospital, Rochester, Minn., whither he had gone for treatment. Dr. Lachappelle was 73 years of age and had a distinguished career. He was practically the founder of Notre Dame Hospital, Montreal, the dean of Laval Medical Faculty, and president of the Dominion Medical Council. He was educated at the Montreal College and the School of Medicine and Surgery and was graduated from that institution in 1865, also receiving the medical degree of the Victoria University two years later. Dr. Lachapelle played an important role during the smallpox epidemic of 1885, espousing the cause of those who favored vaccination, which was not popular among many of his compatriots at the time. He was controller of the City of Montreal for four years. He was a delegate from Canada to the Pan-American Medical Congress held in the City of Mexico in 1896 and acted in a like capacity at the International Congress which took place in Paris a few years later. He was decorated by the Government of the Republic of France. At a special meeting of the Superior Board of Health of the Province of Quebec held on August 6, a resolution was passed eulogizing the deceased physician in the highest terms, as a hygienist, a leader, an administrator, a philanthropist, an economist, and in addition as a most delightful personality. At this same meeting the Board named as temporary president Dr. Arthur Simard of Quebec, and as assistant president Dr. J. A. Hutchinson of Westmount.

A luncheon was given in London on July 10, to meet Sir William Peterson, K. C. M. G., principal of McGill University and its treasurer, and Mr. J. W. Ross. All those present were members of the Medical Faculty of McGill University actively engaged in the war. The chair was taken by Sir Auckland Geddes, K. C. B., Minister of National Service (late Brigadier-General) and Professor of Anatomy in that University. Those present represented only a portion of the teaching staff of McGill University, who were or who had been on active service. Two professors have returned recently to Canada after service overseas. These are Colonel G. E. Armstrong and Colonel H. S. Birkett, professor of Larynology, and Dean of the medical faculty.

At a meeting of the medical faculty of Laval University, Montreal, held on August 7, Dr. L. de Lotbuisere Harwood was elected dean in place of the late Dr. Lachapelle.

As the result of a conference between the members of the Toronto Board of Health and officials of civic milk stations on August 9, some action will be taken to secure powers to have the sale of soothing syrups prohibited. The concensus of opinion was that half of the mothers who come to the notice of the civic health department are killing their children with these dangerous drugs.

3. Fracture of the Long Bones: A Clinical Study. Francis Reder.

2. Studies in Personality Among Feeble-Minded Delinquents Seen in Court.—V. V. Anderson and C. M. Leonard point out that feeblemindedness does not necessarily imply bad social adjustment; that certain persons, though undoubtedly mentally deficient, are able to earn a living, avoid serious social difficulties, and adjust themselves fairly well to the conditions of normal living, and therefore are not necessarily—because they are feebleminded—vicious, incorrigible and irresponsible. They state, however, that the majority of feebleminded delinquents seen in court are institutional cases and are incapable of living up to the social standards of the community. They strongly emphasize the fact that a well rounded, thorough going study of the possibilities of each individual delinquent, though he be feebleminded, is essential for an adequate adjustment of his case. Anderson and Leonard have reached these conclusions as a result of a consideration of one hundred cases of feebleminded delinquents in court. The only stipulation made in choosing the cases was

that sufficient information bearing on the career of the person should be available to determine the general character of the behavior, together with information in regard to the personality sufficient to give a general idea of the abilities and disabilities of the individual. The cases were all adult women, from 17 to 55 years of age. The mental age of these persons was determined by means of the Yerkes-Bridges Point Scale and Goddard's Revision of the Binet Scale. The diagnostic methods employed were: a psychiatric examination to eliminate psychoses, deterioration, etc., and a psychological examination, including the two scales referred to, together with Healy's supplementary tests, the application of tests for school knowledge and general information, and the gathering of a life history bearing upon the careers of the individuals. The case histories furnished evidence of marked differences in behavior, which seemed to correlate less with their age and mental level than with certain fundamental trends of personality. Of the one hundred cases, sixteen were self-supporting, were steadily employed, and apparently gave satisfaction where they worked; thirty-eight, while more or less self-supporting, changed positions frequently, and worked irregularly; thirty-five never worked at all; and eleven did housework at home. Eighteen per cent. never used alcohol or drugs; 82 per cent. used alcohol, and 5 per cent. used alcohol and drugs. Nineteen per cent. were moral, while 81 per cent. were undoubtedly immoral. Twenty per cent. were first offenders, and 80 per cent. were repeaters, among whom a record of 25 to 50 arrests was common. In short, about 19 of these women showed good or fair social adjustment, whereas 81 were considered to have shown poor or bad social adjustment.

5. Hearing Test to Detect Malingering. John F. Callaghan.

5. Hearing Test to Detect Malingering.—John F. Callaghan has evolved the following technique in order to determine whether there is actual deafness in cases suspected of malingering. The basis of his test is the fact that tuning forks vibrating with the same pitch and loudness one inch from each ear are heard in each ear, but if one fork is removed to a point three inches from, let us say, the left ear this sound is lost and only the fork remaining one inch from the other ear is heard. If the latter fork is now removed six inches from the right ear, it will no longer be heard, but the left one will again become audible. Callaghan found that similar results were obtained if a tuning fork were placed against a rubber tubing and his experiments were first conducted with a stethoscope as tube. He now uses a seven-foot length of rubber tubing, hole 3/16 inch, wall of tubing 3/32 inch, to either end of which is attached an aluminium funnel. The funnels are held to the ears, and about one inch away from them, by a simple attachment on the headrest of the examining chair which permits of adjusting them to cover the ears without touching the patient. As the test is one of air conduction, it is important that no part of the apparatus comes into contact with the patient's person at any point. Callaghan found that tuning fork 256 C 1 was heard by the normal ear when placed against the tubing at any point up to 7½ feet from the ear; with a larger size tubing the fork is heard as far away as 30 feet. As a routine, however, he used the 3/16-inch, 3/32 tubing mentioned. The application of the test is as follows: The 7-foot tube is connected with one funnel which is placed about one inch from the right ear. The tuning fork vibrating is applied to the tubing about 6 inches from the ear and is then moved along the tube until no longer heard. The tube is then disconnected from the right funnel and attached to the left and the same procedure followed. After this the tube is attached to both funnels; the vibrating fork is applied to the tube one foot from the right ear and moved along the tube toward the left ear. If hearing is normal, the sound will be heard only in the right ear until it reaches a point about 3 to 3½ feet from the right ear, at which point it will be heard also in the left ear and will continue to be heard in both ears for a distance of about 4 to 6 inches in the middle of the tube; this 4 to 6 inches the author calls the "neutral" space. Beyond this, the sound is heard only in the left ear. Callaghan points out that whereas when the tube is attached only to one ear, as in the first part of the test, the sound is heard for 7 to 7½ feet, when attached to the two ears, it is heard only up to 3 or 3½ feet, because as the tuning fork passes through the neutral space from the right to the left ear, the sound is heard only in the latter ear. As these tests are done behind the patient's back, he does not know whether one or two tubes are being used or which ear is nearer the tuning fork, and it is easily possible to detect any misstatements he may make in regard to his hearing. An 8-foot tubing may be used and may be cut about 14 inches from one end and joined by a simple wooden coupling—such as a meat skewer cut to 2 inches in length and tapered at either end—or, preferably, a coupling of hard rubber tubing. This makes it possible to determine exactly which ear is hearing the sound, as the tube can easily be uncoupled and the fork touched to one end or the other. The degree of hearing can also be determined by this test, modified as follows. Two tubes are taken, each the length of the hearing in the good ear. Funnels are attached to both ears. The fork is touched to the end of the tube connected with the good ear and at exactly the same time a fork is touched to the other tube near the head and is run down that tube. As the fork is touched further away from the bad ear the patient will cease to hear it and, if malingering, will then admit hearing for the first time. This point will be the measure of the distance he hears with the bad ear. Callaghan's test can be applied for bone conduction by the use of lugs, as the vibrations transmitted along the tubing are easily transmitted through lugs to the bony parts in the region of the ear. All that is necessary is to place the funnel in contact with the cranial bones of the ear. In applying the test the author states that he always uses a tube which is 6 inches shorter than the distance of hearing in the good ear of the patient.

1. Righthandness in Its Relation to Visual Conditions.—George T. Stevens points out that though we have no records of more remote antiquity, the early European races of 30,000 years ago were almost unanimously righthanded, as is shown by the greater development of the left side of the cranium in skulls still in existence. He suggests that the custom originated in a realization of the vulnerability of the left side of the body and the necessity of leaving the left hand free to protect that side. As dextrality is still the common custom, asymmetry of the cranium remains and has its effect upon vision. Since the cerebral location for the control of movements of the arm and hand is near the anterior portion of the hemisphere, the more general use of the left hand has resulted in a corresponding increase in development of the left side of the cerebrum at its anterior part, and the upper arch of the orbit is consequently pushed outward and the axis of the cavity changed from a vertical to an oblique direction. The globe of the eye is thereby tilted, its vertical meridian leaning outward toward the temple. This is extremely common, so much so that its absence suggests, but does not prove, lefthandedness. This tilting outward of the

vertical meridian of the eye does not imply any disease, insufficiency, or muscular disability; the eye merely maintains its normal relation to the orbit, while the orbit does not maintain its normal relation to the cranium. The clinoscope has demonstrated that the vertical meridian of the left eye leans outward above; the vertical meridian of the right eye, on the other hand, frequently has a tendency to lean toward the median plane, which has been shown in a large number of cases to be a synergic response to the unconscious effort to adjust the left eye. The positive (i.e. with the upper end toward the temple) declination may occur in the right eye of course, or there may be an outward leaning of the verical meridian in both eyes. As a result of the absence of symmetry of action of the motor influences upon the two eyes, binocular vision is less perfect than it otherwise would be and it is easy to understand that imperfect adjustment of the eyes may work to the disadvantage or dulling of vision. Stevens therefore concludes that the custom of being righthanded is one to be discouraged. This does not mean that children should be taught to be lefthanded, for the case would then be no better; but they should be encouraged to use both hands and no effort should be spared in teaching them to be ambidextrous. It should be remembered also that an unevenly developed brain may strongly tend toward an unevenly developed mind.

5. Sounds Heard in the Auditory Method of Measuring the Blood Pressure: Their Mechanism and Significance.—Clyde Brooks and A. M. Bleile enumerate as follows the phases of sounds heard in the normal adult on raising the cuff pressure to a high level and allowing it to fall gradually: (1) Silence, which may be called the upper phase of silence. (2) Upper phase of murmurs, which are soft and remind one of swirling fluid; they are short in duration and occur at systole. (3) Arrhythmic or desultory snapping sounds or "thumps," which occur at about every third or fourth systole, singly, in pairs, or even in threes, each one corresponding with a systole. They occur at about the end of inspiration or the beginning of expiration, are distinct, snapping, irregular sounds and may easily be overlooked. (4) The phase or regular rhythmic snapping sounds, which grow louder as the cuff pressure is lowered and occur synchronously with systole. (5) The phase of friction sounds or "thump-sh-sh." The double character of these sounds is expressed by "thump-sh-sh." (6) The phase of regular snapping sounds. This may be called the lower phase of snapping sounds and is similar to the fourth or upper phase, the difference being that in the upper the sounds are growing louder, whereas in the lower they are growing fainter, as the cuff pressure is lowered. (7) The lower phase of murmurs, which are more constant and distinct than those of the second phase. (8) The lower phase of silence. A knowledge of the behavior of the artery during compression of the cuff affords an explanation of the mechanism of these sounds. Brooks and Luckhardt showed that during cuff pressure, even at the highest point of systole, an artery does not open at all; this occurs during the upper phase of silence. As the pressure is gradually lowered, the segment of artery that is under the cuff opens with wedge shaped spaces at each end and apple seed shaped spaces at the corners of the flattened tube. The blood currents, as they rush down to these openings, probably produce the indistinct and often unnoticed murmurs. As the cuff pressure is still further lowered, the openings increase in their penetration until at the crest of the systole they break through the occluding pressure of the cuff. The result is the beginning of snapping sounds. Uncertainty still exists as to the mechanism of the production of these sounds. Brooks and Luckhardt suggested that they are due either to the thumping together of two ends of the divided column of blood or to the snapping together of the walls of the artery; another possibility is the snapping open and sudden tension of the vessel walls. The next phase, when the thumps become stronger and regular, may be explained on the hypothesis that as the cuff pressure is lowered it reaches the level where all systoles break through. The friction sound is caused by the blood passing through the narrow slitlike opening of the artery, and as the pressure is further lowered and the opening becomes wider, more blood can squirt through, thus producing a longer and more pronounced friction or nozzle sound, which may overshadow the thump sound. The cessation of the snapping sound is brought on by the still further lowering of cuff pressure which results in the failure of the artery to close completely even at the lowest ebb of diastole. During diastole there is a sudden diminution in the caliber of the artery, and during systole a sudden distention. This produces alterations in the size and shape of the cuff arterial segment which results in vortices and other irregularities in the blood stream, and to these are due the murmurs heard in the seventh phase. From a consideration of the significance of these arterial sounds, the authors come to the following conclusions: That the beginning of regular, rhythmic snapping sounds is the best criterion point for use clinically in measuring the so-called systolic blood pressure; that the criterion for measuring the so-called diastolic blood pressure is the lowest point where the snapping sounds are heard, or where they just cease; and that the auditory method of measuring blood pressure is more satisfactory than the palpatory or sphygmographic methods by the use of such instruments as the Uskoff or the Erlanger apparatus.

2. Gunshot Wounds of the Peripheral Nerves.—Major C. Noon emphasizes the importance of treatment, preoperative and postoperative, in cases of injuries of the peripheral nerves. Under the head of postural treat-

ment, Major Noon points out that a position of relaxation should be maintained in all nerve injuries. In lesions of the musculospiral nerve a Jones's "cock-up" splint, or some modification of it, may be used to relieve the extensor muscles of strain. Operations on this nerve are doomed to failure if the paralyzed muscles are allowed to become overstretched and lengthened by permitting the wrist to be in the flexed position of "drop" wrist. If the wrist is kept in good position, injuries of the musculospiral nerve are among the most favorable for treatment. Electrotherapeutic treatment, including electric treatment and massage, should be employed to preserve the nutrition of the muscles, and it is important that the limbs should be kept warm; it is futile to apply electrical stimulation to cold extremities. Joint stiffness must be prevented by passive movements. Operation, if decided upon, should be done under a general anesthetic. Any lesion of the skin is an absolute contraindication to operation. Application of an Esmarch bandage is not recommended. The procedure is as follows: Skin incision, which should be of ample length; isolation of nerve trunk above and below site of lesion; freeing of nerve at actual site of lesion; passing the sutures and exact coaptation of ends of divided nerve; formation of a sheath at site of lesion; suture of deep fascia and closure of wound. The chief complications met with in the author's series of cases were (a) those due to septic infection of the wounds, extensive destruction of the soft parts, and severe injuries to the bones; (b) extensive destruction to the nerve, resulting in a gap in its continuity, making end to end suture impossible. Drainage and rest for the inflamed parts were relied upon chiefly to overcome the septic conditions. In cases associated with compound fractures Major Noon points out that very careful treatment is necessary if necrosis with development of a persistent sinus is to be avoided. These cases should be thoroughly drained at the earliest possible date, and all loose pieces of bones which have not firm attachment to periosteum removed Carrel-Dakin treatment or continuous irrigation should be employed when necessary. In cases of extensive destruction to the nerve, with care it will usually be possible to perform end to end suture. It is important that the incision should be of ample length, so that the nerve may be separated from the surrounding structure, both above and below the lesion; in lesions of the ulnar nerve it can be displaced in front of the internal condyle of the humerus; and during and after the operation the position of the limb should be that of maximum relaxation, so that all tension is taken off the nerve. When nerve suture is impossible or when the functional result attained by nerve suture is unsatisfactory, this operation may be replaced or supplemented by tendon transplantation, the most favorable cases in which this may be done being those of injury to the musculospiral and posterior interosseous nerves. From a study of 364 cases, 250 of which came under his personal observation, Major Noon has come to the following conclusions: (1) That the diagnosis of an injury to a peripheral nerve ought to be made at the earliest possible time. (2) Successful recovery depends upon early, correct, and continuous treatment. (3) Primary suture should be considered and practised whenever possible. (4) That there should be no unnecessary delay in exploring a nerve if there is sufficient evidence that it has received some injury resulting in a macroscopic pathological lesion. (5) It is almost certain that some macroscopical lesion is present in cases which show no signs of recovery after four months' treatment. (6) That operations on injured nerves should only be done in well-equipped general hospitals, and by those surgeons who have ample experience of such cases. (7) That sufficient attention is not usually paid to the early preoperative and postoperative treatment, and that paralytic deformities and shortened muscles are often the result of ignorance and neglect. (8) That the extreme gravity of an injury to a peripheral nerve is not sufficiently realized by the general profession.

1. Broken Sleep.—Guthrie Rankin comments on the widespread prevalence of sleeplessness since the outbreak of the war. The nervous system of the man on active service breaks under the terrible strain, while the wife or mother at home is worn out by constant mental anxiety. Then there are those who have inherited a gouty diathesis and who are of the neurasthenic type, who find after middle life that their sleep is broken between 2 a. m. and 4 a. m. by a sensation of gastric discomfort. Air raids and other disturbances are also factors which interfere with the normal night's rest. Rankin suggests that the remedy for insomnia in many cases may be found in attention to the details of routine habits and abstention from serious work after dinner. A tablespoonful of paraffin before breakfast will lubricate the intestine and keep the bowels in order, and once or twice every week 1 grain of calomel with ⅓ grain of extract of colchicum made into a pill with 3 grains rhubarb or colocynth will provide for hepatic efficiency. A mild aperient water may also be used. To prevent gastrointestinal fermentation, he suggests periodical courses of about two weeks of 3 grains each of charcoal, betanaphthol, ox gall, guaiacum, taken in capsule form forenoon and afternoon. The evening meal should be light and meat and tea taken only once a day; a glass of some light wine may promote digestion, and an ounce of brandy in hot milk, arrowroot, or Benger's Food may be useful as a nightcap. Whenever possible of course, drugs should be done without, but suitable drugs, wisely chosen, should be given if necessary. Bromides should be administered in full doses of 30 grains and are more efficient if combined with small doses—ten grains—of chloral hydrate. The influence of this drug upon the cardiac centers Rankin believes to have been grossly exaggerated. If this combination fails, bromidia in dram doses, chloralamide in 30-grain doses, or chloralose in 6-grain doses may be tried. Other alternatives are: Medinal, 7 grains; trional, 15 grains; sulphonal, 20 grains; adalin, 10 grains; chloretone, 15 grains; or bromural, 10 grains. Paraldehyde is valuable in cases where there is mental excitement and extreme restlessness. One-quarter grain of morphine with 1/100 grain of atropine, administered hypodermically, is indicated in cases where pain contributes to the sleepless nights. Rankin points out that the abuse of morphine is no argument against its legitimate use; it will bring relief when other remedies are of no avail and should not be withheld because of the possible creation of a drug habit. Whatever hypnotic is chosen, the best results are obtained by giving it three or four nights in succession rather than leaving it to the patient's judgment to take as he pleases. If often happens that better results are obtained by the administration of two or more hypnotics instead of any one by itself, and Rankin mentions the following: 15 grains trional with ½ grain of codeia; 20 grains chloralmide with 30 grains potassium bromide; 10 grains aspirin with 7 grains Dover's powder; 10 grains bromural with ⅙ grain morphine; 5 grains zinc valerianate with ¼ grain heroin. He adds that in cases with persistent high-tension pulse dependent upon sclerotic changes in the arteries, nitroglycerine is of inestimable value. A tabloid containing 1 minim of a 1 per cent. solution of the drug should be put into the cheek the last thing at night and left there to melt gradually. It prevents increase of tension during sleep and may be repeated should the patient awake during the morning hours. Electricity may be useful, but its effects are uncertain. Hypnotism Rankin considers a doubtful and experimental remedy, which may be of some value in carefully selected cases. He adds that it is well to recognize the value of philosophy as a hypnotic.

Experiments with the Treatment of Malaria, Particularly the Quinine Resistant Cases.—C. Seyforth be-

lieves that it is necessary to prevent the quinine habit by exhibiting the drug in interrupted series of treatments. Here is the typical treatment as advised by the writer: During eight days one gram of quinine is given by intramuscular injection daily, then five days' rest; eight days, one gram of the drug is given by mouth daily in fractional doses, then five days' rest. Two days a one-gram dose is given, then five days' rest. Then one gram is given two days each week for six to eight weeks. Old or badly treated cases are benefited by a combined treatment of quinine and neosalvarsan, the writer proposing the following method. An intramuscular injection of one gram quinine is given daily for four days, and on the morning of the fifth 45 centigrams neosalvarsan and in the afternoon 1 gram of quinine are given by intramuscular injection; then for three days one gram of quinine daily by intramuscular injections and then five days' rest. Next one gram quinine is given daily *per os* for two days, then five days' rest and after this the treatment is continued as already mentioned above. Chronic cases which have been treated with insufficient doses of quinine should first be severed from the drug for two to four weeks before taking it again. Manifest cases, with the plasmodium in the blood, are more accessible to treatment than the more or less latent ones; therefore it is well to provoke the entrance of the organism into the circulation. Arsenic is necessary during convalescence in order to renovate the blood.

Observations on the Resistance of Hematozoa to Quinine.—C. Seyforth mentions several possible causes in cases where quinine has proved itself useless. In the first place, the drug may be insufficiently absorbed (vomiting, diarrhea, constipation), the quinine itself being the cause of these disturbances. Intramuscular injections of the drug in these cases shows that the pretended inactivity of the drug does not exist. The mixed infections (typhoid, dysentery) may conceal the drop in temperature. A true acquired habit to the drug may exist in the plasmodium or the organism and is the result of prolonged but insufficient doses of quinine. It likewise explains the general weakness of these patients and the particular virulence of certain races of the plasmodium.

June 11, 1918.

Interpolated Ventricular Extrasystoles and the Theory of Contraction from Excitation.—H. Straub endeavors to show by electrocardiographic tracings taken in a case of extrasystolia that each extrasystole is followed by a prolongation of the auriculo-ventricular interval for the following systole. This prolongation is not to be attributed to a slowing of conduction but to an increase of the latent period of ventricular excitation.

An Operative Procedure for Radial Paralysis.—Guetsche proposes to correct the position in flexion and the impotency which results from shortening of the paralyzed extensor tendons. In two cases he has also been able to bring the hand into the position of moderate flexion, thus relieving the drooping which existed before the operation. The thumb is no longer in apposition with the palm and the fingers are in slight flexion. In this position, when the hand is opened, the patient is unable to execute any movement of extension, but as soon as he closes the fist the entire hand becomes raised on the forearm. This combination of extension of the hand with flexion of the fingers is eminently favorable for the function of prehension. The writer is unable to say whether or not the phenomenon observed is to be explained by the reëstablishment of a certain amount of functional activity of the extensors or by a purely mechanical action derived from the new position given to the hand.

Clinical Studies on the Functions of the Thyroid.—E Herzfeld and R. Klinger come to the following conclusions: (1) The thyroid secretion cannot be an albuminoid body, but a dialysable product of disintegration. (2) Goitrous degeneration is to be explained by an insufficient autolysis of the cell albumin of the gland. (3) Iodine is united to the products of albuminous disintegration and is not an essential part of the secretion; it merely acts as an agent favoring the formation and excretion of the secretion. (4) The effect of the nerves consists in an increase of the hydrolytic process in the cells.

Deutsche medizinische Wochenschrift.

June 6, 1918.

The Operative Treatment of Pulmonary Tuberculosis.—Schottmüller is absolutely in favor of treating unilateral pulmonary tubercular lesions by bringing about compression of the diseased organ. Besides pneumothorax, the writer describes two procedures which are to be resorted to when pleural adhesions are present. One consists of a thoracoplastic operation, the extensive resection of several ribs. To show the admirable effect of this operation Schottmüller reports *one* case. The second procedure is rather more personal with the writer and consists in a modest costal resection sufficient for the introduction of the hand into the thoracic cavity for the purpose of manual breaking up of adhesions. After suture, the results obtained by the interference are maintained by injections of nitrogen under very high pressure. Schottmüller says that this procedure has resulted in a marked improvement, also in a single patient.

On Spontaneous Pneumothorax in Non-Tuberculous Subjects.—This question is discussed in two articles, one by Teske, the second by Cahn. The discussion bears upon the mechanism of the production of superpressure in the involved pleura (it is entirely confined to *closed* pneumothorax). Cahn wishes to explain the process by the inspiratory effort which little by little aspirates the pulmonary air into the pleura. From this it appears that he does not take into consideration the production of a positive pressure in the two phases of respiration. Teske, with more reason, admits that the play of the pressures in a diseased pleura is determined by the respiratory play of the healthy lung. At inspiration the air is inspirated into the diseased pleura, while during expiration the healthy lung forces the air into the diseased organ by virtue of the greater elasticity conferred upon it by its normal condition. The narrow fistula acts like a valve so that the passage of the air can only take place in one direction, namely, from the bronchi to the pleural cavity.

Treatment of Pulmonary Hemorrhage by the Sitting Position.—Von Niedner thinks that a hemorrhage resulting from a stasis in the pulmonary domain should be treated with the patient out of bed, seated in a chair. On the contrary, a hemorrhage due to rupture of a vessel should be treated by absolute immobility in bed.

Deutsche medizinische Wochenschrift.

June 13, 1918.

Cleansing and Disinfection of the Hands.—F. Neufeld has undertaken to verify the effect of various procedures of hand cleansing, the hands having first been infected. His results appear quite paradoxical in several points, namely, the superiority of alcohol over other disinfectants upon the condition that it is not too concentrated; the uselessness of brushing with a nail-brush, this being more applicable in gross soiling of the skin than to its tenor in bacteria. The reputation of tincture of iodine is greatly exaggerated, he says. Hands infected with the *Bacterium coli* are better disinfected with sublimated alcohol at 1/10 per cent., then come alcohol and alcoholic soap (containing 80 per cent. alcohol). The chlorite solutions, namely, Javel water at 3 per cent. and Dakin's solution, take the last place from an exclusively bactericidal standpoint. The use of the brush and washing with soap hinder the subsequent action of alcohol. Alcohol quickly kills bacteria; its effect is by no means due to the fixation of the germs. Its action on the spores is very greatly inferior to that of other antiseptics. The writer does not believe, for that matter, in the possibility of fixation of bacteria. For example, mastisol becomes rapidly dissolved on the cutaneous surface and gives free vent to the exit of the microorganisms. Washing with soap, although not sufficient for surgical disinfection, is of great value in hygienic prophylaxis. As a substitute the writer has obtained good results with lime (one

or two spoonfuls taken in the hands and mixed with water). This procedure will even result in a more effective sterilization than with soap itself.

How to Be Sure of the Cure of Gonorrhea in the Male.—Zieler is of the opinion that the best means to attain this end is to dilate the urethra with a Kollmann instrument. After this has been done the urethral discharge should be examined microscopically for four or five days in succession. The injections of vaccines will render the procedure still more sensitive.

Le Progrès Médical.

May 18, 1918.

The Gauze Mask in the Prophylaxis of Contagious Diseases.—Bernard first refers to the original use of the blouse by those exposed to contagious disease in hospitals. This was put on before the exposure and afterward removed. Protection with such a resource was of course confessedly incomplete. At that period not much was known of carriers. An attendant, himself perhaps immune, could receive and harbor infectious matter projected from the throat and nasopharynx, while if not immune he could contract the disease himself. A radical prophylactic resource consists of the isolation of patients in sterilizable cubicles. A similar resource used to some extent is draping the bed with mosquito netting which is sprinkled thoroughly with weak solution of eucalyptol. Naturally such methods of isolation are indispensable when victims of different contagious affections are confined in close proximity. It has been successfully used in the army. During the present year Weaver, an American practitioner, has caused a gauze mask to be worn by the hospital personnel in connection with cerebrospinal meningitis. This idea is of course far from new, for surgeons have frequently included this simple device under aseptic technique. The experiment proved instructive, for not a carrier developed among the exposed personnel (as a rule 12 per cent. of the exposed become carriers). The measure was extended to diphtheria wards, with the assistance of the Schick test. The per cent. who became carriers was thereby reduced from 23 to 8.2, while not a single case of infection occurred during the observation period of two years. An experience with the gauze mask of six months in the scarlatina wards with 73 nurses exposed was quite negative although an average of three nurses annually had been contracting the disease.

Vincent's Angina.—Chalier seeks to gain some idea of the frequency of this affection. If we reckon by percentages of cases of sore throat, the disease is rare, for both Vincent and Simonin found it to be a little over 2 per cent. In civil practice it is certainly rare in hospitals. In a large service one may hardly see a case a year. But the incidence of the malady is so large among soldiers as almost to make of it a military one. A peculiar feature is the tendency to relapse, so that one soldier may represent three or four cases. It has occurred clinically as a stomatitis. The author has had charge of 2500 men over a period of 22 months and has treated 46 cases of angina with an average absence from service of 4 or 5 days (cases with but 1 to 2 days' absence are not included). Of these 46 cases 13 were examples of Vincent's disease—over 28 per cent. as against 2 per cent. in civil practice. The fact of contagion in individual cases is well established.

Cholera Nostras Syndrome in an Alcoholic with Degeneration of the Liver.—Lesieur and Jacquet treated a man of 43 employed in auxiliary military work for what appeared to be cholera. There was no suspicious case in the camp, however, and the algid, collapsed patient was thought to have acute inflammation of the adrenals, a crisis of uremia or perhaps an anomalous form of spirochetic icterus or finally a poisoning from without. Of these four possibilities the latter appeared the most probable—suicidal poisoning. The patient could not be saved and autopsy appeared to justify the diagnosis. There was an intense hemorrhagic gastritis with recent well marked degeneration of the liver. In the intestine, however, were found evidences of an infection, due probably to the bacillus proteus. To explain the fatty change in the liver, which might have been produced in acute phosphorus poisoning, the patient was an alcoholic who drank much champagne. Such a sequence is rare, but the author has seen it a number of times in hard, daily drinkers. Apparently the same factor, when less massive, produces the interstitial lesions of hepatic cirrhosis. The insufficiency of the liver was probably the predisposing cause of the proteus infection.

Norsk Magazin for Laegevidenskaben.

April, 1918.

Constitutional Hypersensitiveness and Asthma Bronchiale.—De Besche states that in 31 cases of asthma 12 presented a definite relationship to certain animals, viz.: 11 to horses and 1 to cats. A thirteenth case presented relationship to some vegetable sensitizing agent —presumably wheat. In the other 18 cases no animal or vegetable protein sensitizing agent could be discovered. In horse asthma a peculiar conjunctival reaction is obtainable, as follows: One places a finger tip on the skin of a horse and then touches the conjunctiva bulbi of a patient subject to horse asthma. At once redness, lacrimation and slight edema appear. In 5 cases a cutaneous reaction also developed. When a drop of horse serum is applied to a vaccination scratch a bleb develops. In the case of cat asthma both conjunctival and skin reactions were obtainable. In a case suffering from horse asthma an injection of 2 c.c. of antidiphtheritic horse serum produced a state resembling anaphylactic shock in a guinea pig. After recovery the patient was free from horse asthma for 4 months—could drive a horse or enter a stable or circus with impunity, but eventually the affection reappeared. By injecting 5 c.c. of blood serum from a patient with horse asthma into the peritoneal cavity of a guinea pig the hypersensitiveness to the horse protein may be passively transmitted to this animal. In some cases of horse asthma the asthma is due entirely to the horse, while in other cases it is also set up by the presence of other animals —cow, sheep, rabbit, dog, etc. Others again are hay fever subjects, and one patient exhibited asthma after eating strawberries. Some horse asthmatics are ignorant of the fact that their asthma is due to the horse, and in such cases the eye and skin reactions are of value. Others have known the nature of their asthma from early childhood and still others knew that the hypersensitiveness to the horse was a later development. In one case asthma was accompanied by mild colic and diarrhea, in another by vomiting and abdominal pains, and in certain individuals these manifestations appear not as complications but equivalents. Horse asthma is not *per se* familial but may occur in several members of families with family tendency to bronchial asthma and hay fever. While spoken of familiarly as animal protein, the sensitizing substance does not so behave as it is volatile and can be present in dandruff and perspiration. It is very dangerous to inject antidiphtheritic serum from horses into subjects with horse asthma but there appears to be no danger in asthma of other origin nor in hay fever subjects, especially after the reactions, eye and skin, are negative.

Mortality of Physicians in the United States.—During the year 1917, 2300 deaths occurred among the 160,000 physicians of the U. S. and Canada, a rate of 14.37 per 1000.—*Cronica Medico-Quirurgica.*

Peripheral Nerve Injuries.—Desconts formulates the proper method of dealing with soldiers who have been invalided with these lesions. The results thus far have left much to be desired and in future it will be well to have no fixed periods for hospital sojourn, but simply place the men in special observation services. No victim should be sent to a physiotherapeutic institute until he has been in an observation service under the care of a neurologist. At this period he may be fitted with prosthesis if he can benefit from it. When they are referred to the physiotherapeutic institute it is not for a specified time, but long enough for wound regeneration to occur and voluntary motion reappear. When it has become evident that there will be no functional recovery the soldier is retired on his pension. During long periods of observation or treatment the soldier should receive a week's furlough every four months. —*La Presse Médicale.*

Book Reviews.

Les Fractures de Guerre du Maxillaire Inférieur. Par Le Dr. A. Herpin, Chef de Service de Stomatologie de la 18e Région (Centre de Bordeaux). Avec 100 gravures dans le texte. Price, 4 fr. 40. Paris: Librairie Félix Alcan, 1917.

Fractures of the lower jaw have been rather numerous during the present war, hence there has been an unusual opportunity to study them and to test the various methods for their reduction and retention. The department of which the author was chief cared for 921 fractures of the inferior maxilla in the course of one year, and this book is written on the basis of a very large experience in handling such fractures.

The anatomy, the physiological action of the various muscle groups and individual muscles attached to the lower jaw, pathology, symptomatology of lower jaw fractures in general and those in the various portions of the bone, processes of repair—all these subjects and more are considered in detail before taking up the methods of treatment.

The method employed by the author for fractures in each part of the bone and with various degrees of loss of substance is discussed and thoroughly illustrated. Though there are other methods that will be preferred by many, the results claimed by the author are certainly remarkably good. Whatever methods of treatment one prefers, the book presents the entire subject well, contains many valuable suggestions, and is well worth reading.

American Addresses. By Sir Berkeley Moynihan, M.S., F.R.C.S. 12mo of 143 pages. Price, $1.75 net. Philadelphia and London: W. B. Saunders Company, 1917.

This volume contains five addresses delivered by Sir Berkeley Moynihan during his recent visit to this country. Several, if not all, have been published in the medical journals; but it was a happy thought on the part of the publishers to combine them in one volume, for they are all exceedingly interesting and, with the exception of the first, deal with surgical problems that are likely to engross a fairly large percentage of our profession before the war is ended. The titles are: The Causes of the War; Gunshot Wounds and Their Treatment; Wounds of the Knee-joint; On Injuries to the Peripheral Nerves and Their Treatment; and Gunshot Wounds of the Lungs and Pleura.

In every one of the surgical conditions discussed methods of treatment have changed, sometimes radically, during the progress of the war, and Moynihan has summarized the situation in each case in his usual masterly fashion. Certainly all who have not already read and possess copies of these addresses in some form will be well repaid for securing this book.

A Practical Text-book of Infection, Immunity and Specific Therapy. With Special Reference to Immunologic Technic. By John A. Kolmer, M.D., Dr. P.H., M.Sc., Assistant Professor of Experimental Pathology, University of Pennsylvania; Professor of Pathology and Bacteriology, Philadelphia Polyclinic, and Pathologist to the Department of Dermatologic Research; Pathologist to the Philadelphia Hospital for Contagious Diseases. With an Introduction by Allen J. Smith, M.D., Sc., Ll.D., Professor of Pathology, University of Pennsylvania. With 147 original illustrations, 46 in colors, by Erwin F. Faber, Instructor in Medical Drawing, University of Pennsylvania. Second edition, thoroughly revised. Price, $7.00. Philadelphia and London: W. B. Saunders Co., 1917.

To those who are familiar with the first edition of Kolmer's book no words of commendation are needed for the present volume, which follows the same general plan as the previous one and includes several additions that bring the work up to date. Among the new subjects found in this edition may be mentioned the following: the Shick toxin test for immunity in diphtheria, and active immunization in diphtheria with toxin-antitoxin mixtures; complement fixation in tuberculosis; a quantitative Wassermann reaction; Lange's colloidal gold test; and blood transfusion. Many other topics have been amplified and rewritten to fit in with advances made since the appearance of the first edition. The research work which the author has carried out with the aid of Drs. Schamberg and Raiziss on salvarsan and allied synthetic preparations, particularly with regard to their toxicity, is considered in detail. The book covers a great deal of ground both theoretical and practical. It is divided into five parts. Part I deals with general immunological technique, laboratory equipment, animal inoculation, and the preservation of serums. Part II is devoted to a discussion of the principles of infection. Part III takes up the principles of immunity and special immunological technique. In this part the theoretical basis of immunity is first considered. Following are several chapters on the different kinds of immune substances with their methods of detection, and practical application. The chapters on the various types of complement fixation are especially worthy of note. Here the laboratory worker will find much valuable information well set forth and extensively illustrated. In Part IV applied immunity in the prophylaxis, diagnosis, and treatment of disease, bacterial, serum, and chemotherapy are dealt with. Part V comprises exercises and experiments on infection and immunity; this part is particularly designed for medical students.

Leçons Pratiques d'Alimentation Raisonnée. Par Armand Hemmerdinger. Prix, 1 franc 25 centimes. Paris: Masson et Cie., 1918.

This little volume is semiofficial in origin, having been published under the auspices of the Société Scientifique d'Hygiène Alimentaire. The significance is far greater than a work of this kind would ordinarily suggest, because there is embodied an effort to secure daily calories from substitute foods in place of staple commodities. The cheapest calories are seen to be obtainable from bread, rice, dried onions, breast of mutton, cocoa butter, chestnuts, sugar, etc., which cost in a menu less than one franc daily. At the other extreme, costing over three francs daily, are potatoes, eggs, gruyère cheese, lean beef, rabbit flesh, and carrots.

Les Blessures du Cerveau. Par Charles Chatelin. Préface du Pierre Marie. Deuxième édition. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1918.

The first edition of this work comprised a separate monograph. "Traitement opératoire des plaies du crâne," by T. de Martel. Each of the two productions is now separately published, so that the present volume is practically a new book, the original having been revised and augmented. It comprises 200 pages, illustrated by thirty-nine text figures and two plates. The wounds of seven separate areas are separately considered, in addition to symptoms common to all and various complications.

Les Premières Heures du Blessé de Guerre. Par P. Bertein et A. Nimier. Préface du Médecin Inspecteur Général Jacob. Collection Horizon. Prix, 4 francs. Paris: Masson et Cie., 1918.

In the first chapter of this volume we find a necessary description of a modern battle. Next are considered as separate entities the wounded soldier and his wound. The third chapter covers the evacuation from the front to the *poste de secours*, including first-aid dressings. The static aspect of the *poste* is described in detail with the changed conditions which are initiated by a battle. Chapter V covers conditions already abundantly described elsewhere, to wit: the actual treatment of the wounded. A postscript deals with the Sanitary Service at the battle-front.

Therapeutic Immunization Theory and Practice. By W. M. Crofton, M.D., Lecturer in Special Pathology, University College, Dublin; Visiting Physician, Royal National Hospital for Consumption in Ireland; Pathologist to Dr. Steevens' Hospital; late Temp. Capt. R. A. M. C. Price, $2.50. Philadelphia: P. Blakiston's Son & Co., 1918.

The book contains the substance of the lectures Dr. Crofton has delivered during the past seven years at University College, Dublin. Perhaps the feature of the book is a description of a more complete theory and practice of vaccine therapy founded by the author, on account of the general belief in the medical profession that this form of treatment is a comparative failure. The book is decidedly interesting.

Society Reports.

AMERICAN THERAPEUTIC SOCIETY.

Nineteenth Annual Meeting, Held at Richmond, Va., June 7 and 8, 1918.

DR. W. WAYNE BABCOCK OF PHILADELPHIA, IN THE CHAIR.

(*Concluded from page 352.*)

Second Day—Saturday, June 8.

A Clinical Study of the Variable Therapeutic Potencies of the Galenicals and Their Inherent Unreliability.—Dr. HARRY BEATES of Philadelphia presented this communication. (See page 357.)

Clinical Observations on Ouabain.—Dr. ERNEST ZUEBLIN of Cincinnati read this paper. (See page 359.)

Neurocirculatory Myasthenia.—Major ANDREW MCFARLANE of Albany, N. Y., gave an informal talk on a certain class of cases encountered in the army camps, which he designated "neurocirculatory myasthenics." His presentation, he said, reminded him of a negro soldier, at a Camp, who gave his name as "Extra" Routledge. When asked why he was called "Extra" he said "Well, you see, doctor, my mother had 6 children, and then I turned up unexpected like, and she called me "Extra." The society could call his remarks "extra." Dr. McFarlane said he was not a heart specialist, nor did he claim to be. He was chosen by the Surgeon General to do heart work and he was kept busy at it. His work was among the National Guard from North Carolina, South Carolina, and Tennessee. They were poor specimens and 33 per cent. of them had hookworm. All were anemic from malaria. Diet, it would seem, was poor in the South, and the men were worse nourished than the corresponding class of Northern soldier. In the process of training many of these soldiers broke down. The efficiency of the army depending on the ability of the unit, it became the duty of the medical officer to determine which men could be made into efficient soldiers and to eliminate those who would be sure to break down. It would not do to have these men drop out after they had been transported 3,000 miles. It was also unwise to deprive the State of a self-supporting civilian, who, at best, would make only a "near soldier." Exophthalmic goiter, tuberculosis, tachycardia would obviously unfit a man for performing the soldier's task. Preliminary examination was necessarily rapid, 15,000 recruits were examined in 9 days by 7 medical men, at a rate of 1,800 a day. Two men were employed in making a final examination. Under these conditions only manifest cardiac lesions could be detected, and in a few weeks soldiers not able to keep up with their work would complain to the army surgeon. Often it was difficult to determine with justice the claim of these men, and doubtful cardiac cases were graded in a separate detachment. A little camp of ten tents was instituted and 41 soldiers were placed under observation. Five of these were returned to command, and ten were referred to the board. The remaining 29 were recorded as inefficient soldiers, but no determining lesion was found. There was cyanosis, coldness, and sweating of the hands; tremor; sweating under the arms; marked thrill in the precordium; a booming sound over the apex; mental instability; breathlessness after exercise; and abnormal exhaustion. It was necessary to adopt some standard to determine the efficiency of the men and for this a French code called "Pignet's Formula" was adopted. The author of this schedule was a contemporary French Surgeon and Dr. Blake had translated the work into English. It was supposed to be an invaluable aid in the French Army. It was compounded of the relationship of the height in centimeters to the weight and chest measurement and maximal expiration. The resulting calculation was: 10 = strong; 25 = fair; 25-30 = weak; 35 = very weak; + 35 = useless. This formula was tested in the 29 cases mentioned. The result was: 1 strong; 2 good; 5 fair; 6 weak; 6 very weak; 9 useless, according to their physical measurements. The board, however, had refused to discharge these men because no diagnosis could be made. Only one of the 29 was strong. Examination was next made by dentists and other specialists. Infections were found in every case. Some had double infections of teeth and tonsils. Examination of the blood in a few cases, before and after a two hours hike, gave an increase of leucocytes from 8 to 15 thousand, one hour after exercise. These cases, while few in number, represented a large group of potential inefficients. They were a group of substandard men who had been subjected many years to a low grade infection. Suddenly they were thrown into a new environment. These three factors occurring together forced the man to break down. Sir Thomas Lewis had established the prognosis and diagnosis in these cases. The only treatment was by gradually progressive exercise. The disability was half constitutional and half toxic in origin. Fifty per cent. of these men would never be fit for front line or any other military work. They would become a burden and it was for the medical man to weed out those who never could become fit soldiers. These patients were not seen in civil life because they naturally fell into the line of least resistance. They drove wagons, or chose some other easy task where they felt well and had to make no effort. Lewis had called this lesion "effort syndrome." It occurred in one out of every two or three hundred cases. Dr. McFarlane said he had named it "neurocirculatory myasthenia." This term was his own child and he was naturally proud of it. Some of these cases could be built up, and by attention to teeth and tonsils and by graduated exercise could be restored to normal. Each man was exercised according to his own weight according to the Pignet chart. All the soldier had to do was graded according to his own physique. Much of scientific value would be discovered about these cases by keeping them under rigid observation. There was a marked tendency to introspection and mental depression in the psychology. Some of them could be retained, others would have to be returned, but all would be better and wiser men for their experiences in the army.

The Place of Ipecac in the Treatment of Auricular Disease.—Dr. L. F. BISHOP of New York presented this communication. (See page 356.)

Some Points in the Management of Heart Disease.—Dr. E. E. CORNWALL of Brooklyn, New York, read this paper. (See page 353.)

On the Differentiation of Auricular Fibrillation and Flutter and Their Treatment.—Dr. THOMAS E. SATTERTHWAITE of New York presented this paper. He offered the following as a simple classification of the cardiac arrhythmias: (1) Sinus or vagus arrhythmias; (2) extrasystolic arrhythmias; (3) heart block; (4) Adams-Stokes disease; (5) auricular fibrillation with its subvarieties, flutter and flicker; (6) ventricular fibrillation; (7) pulsus alternans. The auricle, he said, is a sac with thin walls, a reservoir and not a pump. Fibrillation of the auricle had never been traced to a pathological sinus. The following were the signs of auricle fibrillation and flutter: (1) A pulse deficit in which a large number of ventricular contractions are not felt in the pulse at the wrist; (2) complete lack of coordination between the jugular and radial pulses; (3) great variation in strength between the beats, best shown by the electrocardiogram; (4) complete lack of uniformity between the interventricular intervals; (5) usually a rapid action of the heart; (6) control of this condition to a large extent by digitalis or strophanthus. In the differentiation of auricular fibrillation we had to distinguish it from the other arrhythmias above noted. Sinus arrhythmia was merely a temporary variation from normal within physiological limits. Extrasystole arrhythmia was of varying types; the distinction between the auricular and ventricular types could be made with the electrocardiograph or polygraph only. In heart block there was a slow arterial pulse as compared with the venous. In Adams-Stokes disease there were syncopal attacks. Ventricular fibrillation was extremely rare; in it the normal ventricular waves were supplanted by a series of large waves of peculiar character. Pulsus alternans, when well developed, could be distinguished by the finger, but always definitely by means of the electrocardiograph or polygraph.

Dr. JACOB DINER of New York said that Dr. Beates' paper on the physiological standardization of drugs

was of considerable importance to the pharmacologist. There was, however, no uniformity as to the best method of standardization. Many methods had been suggested, but until pharmacologists were united in their suggestions pharmacological control was an impossibility. Where the Pharmacopœia was used as a guide the Pharmacopœial Committee might be responsible for any damage done. If they stated the maximal dose that could be given they might legally be held responsible for ill effects to any patient who might be susceptible to a given drug. Therefore, an average dose was in all cases stated. It was assumed that the practitioner would know best how to employ the physiological dose in a given case. No drug had a given dose. There were always examples of different inactivity. In the laboratory one could only take the average according to the number of animals employed. One never based conclusions on a single animal. There were idiosyncrasies in animals as well as in human beings. The duty of the physician was to determine the given dose for a given patient. In regard to Pignet's formula, he presumed that the metric system was used, and not inches and pounds, or the latter would give a minus quantity.

Dr. Douglas Vander Hoof of Richmond, Va., said that these papers were excellent and entertaining. All were indebted to Dr. Satterthwaite for the valuable work presented in cardiovascular investigation. The principles governing arrythmias had only been worked out within the last ten years. To many men, certain types still were confusing. The sinus arrythmias in children were very common. One was called by the anxious parents, who had put the child to bed for irregularity of the heart action. These children did not need treatment for the heart, but they needed hygiene, and plenty of exercise. Putting them to bed did more harm than good. Dr. Bishop's paper on ipecac was an eye opener. Had he used ipecac without digitalis in these cases? Dr. Beates had presented a well-timed paper. The great vice of the profession was apathy. They all went back and prescribed galenicals which had been shown time and again to be unreliable. Dr. Beates had done distinct service in presenting this communication. The older men had been accused of using placebos. The doctor gave bread pills to fool the patient, and the patient threw them out of the window to fool the doctor. The same thing practically was done now, only unintentionally. By prescribing galenicals the modern doctor was giving placebos. The doses prescribed in many textbooks were absolutely innocuous. In achylia, one or two minims of hydrochloric acid were prescribed, instead of one or two drams. All had been greatly impressed by Dr. McFarlane's talk. These cases were occasionally seen in civil life. One would have been glad to have had more extensive laboratory investigations in those cases cited. The designation of "neurocirculatory myasthenia" did not cover the whole question. They were dealing with a focus of infection—teeth, tonsils, etc.—and unless a routine Wassermann was made there were still points to be cleared up. Many of these patients would show achylia, on gastric analysis. They had achylia gastrica with secondary intestinal toxemia. They often showed a secondary vasomotor instability. Dr. Cornwall's advice as to rest in the cardiac cases was very commendable. In all cases prolonged rest was not possible. In the cases of cardiopaths, business men who found it impossible to leave their business entirely, one day each week in bed gave them a good measure of rest and comfort. Staying in bed each Wednesday and half the day on Sunday was extremely helpful. He would like to hear more of the lacto-vegetarian diet, as advocated by Dr. Cornwall. Did this lower blood pressure? Dr. Vander Hoof had one patient, an extremely successful lawyer, aged 35, at the top of his profession, of excellent physique and habits. Life insurance examination disclosed the fact that he had a blood pressure of 200 systolic, and retinal hemorrhages. He went to Nauheim and was put upon a diet of milk, cereals, and vegetables. He was on that diet till death two and one-half years later. The blood pressure remained constant, and he died of cerebral hemorrhage. Another patient, a woman of 52, leading a most careful life, had a systolic pressure of 210. This remained constant in spite of diet. These facts made the question of diet and blood pressure rather confusing. It would seem as if diet played a very minor part. Dr. Vander Hoof said he would be glad to be convinced if some one would furnish proof that diet did lower blood pressure.

Dr. Ernest Zueblin of Cincinnati said that he was much interested in the *x*-ray pictures of the bulging of the right heart in auricular heart lesions, as shown in Dr. Satterthwaite's series. Although in his personal opinion the advantage of stereoscopic *x*-ray plates over flat plates in the dissociation of *x*-ray shadows were evident, he called attention that in chronic heart disease the adjoining lung presented also an infiltration which on a flat and single plate may be ascribed as belonging to the heart and pericardium proper. Such a density might be due to circulatory disorders in the lung itself and with the increased cardiac action of the heart could reveal a pulsating movement. In regard to the instability of the drugs, he was very much pleased to see his opinion confirmed by other investigators. He had already published part of his studies of radioscopic examinations of drugs, which experiments showed the gradual decrease of radiation corresponding to the lessened therapeutic activity. These drugs even protected from light, from humidity, and kept at constant temperature for months and years revealed the same process of disintegration. In his opinion great stress had to be laid upon fresh and well preserved drugs in order to obtain better therapeutic results. He demonstrated charts of digitalis and strophanthus preparations which had been tested at various periods, illustrating the gradual deterioration.

Dr. Cornwall said that Dr. Vander Hoof's question, if the "easy diet"—*i.e.* the regulated nearly or quite lactovegetarian diet—really did produce the results claimed, was a pertinent and vital one; and in answering it he would say that there were few conclusions in medicine based on clinical observation that seemed surer to him than that this easy diet greatly relieved the symptoms of cardiovascular disease and prolonged life and usefulness. In fact, where there was any serious sickness, either acute or chronic, an easement of the dietetic burden was rationally called for; even the animals knew this, and stopped eating for a while when they were sick; and the loss of appetite which was naturally present in most diseases was a rational suggestion of nature. In regard to the conditions with high blood pressure, most striking results often followed the taking of the easy diet, with little or no animal flesh in it; for reducing to a lower plane and keeping there a persistently high blood pressure, this diet was far and above the most effective thing. Of course there were some cases with high blood pressure which no modification of diet could relieve, but they were cases of advanced nephritis or arteriosclerosis or particular circulatory obstruction which imperatively called for the high pressure as a compensatory thing. In regard to strophanthin, Dr. Cornwall said that when the larger doses were given hypodermically morphine often was also called for, and could be given in the same deep injection, thereby relieving the pain of the injection, when that was prominently present; but he wished here again to record his observation that strophanthin did not always or regularly produce severe distress when deeply injected, and that often it did not produce enough disturbance to cause the patient to complain about it; especially if the strophanthin was dissolved in a full hypodermic syringe of water and thus injected. In regard to the use of belladonna, was it not possible that the employment of hyoscyamus might be preferable for the use indcated? Some authorities believed that the latter had less tendency to dilate the pupil and affect the accommodation than the former. The alkaloids in belladonna consisted principally of a mixture of atropine and hyoscyamine, the latter being readily transformed into the former, and practically identical with it in action. The important constituents of hyoscyamus were the alkaloids, hyoscyamine and hyoscine, the former existing in much larger amount than the latter. Hyoscyamine, as just stated, was practically identical in its action with atropine. Hyoscine, or scopolamine, as it is also called, resembled atropine in its action when applied to the conjunctiva, except that the effect passed off more quickly. Possibly this fact accounted for the opinion of some observers that hyo-

scyamus had less tendency to interfere with the pupil and accommodation of the eye than belladonna. Referring to bismuth preparations, some years ago he had occasion to investigate the comparative spreading properties of bismuth salts as ordinarily occurring on the market with the so-called cream of bismuth, milk of bismuth, or lac bismuthi, a non-proprietary preparation of basic carbonate, made by precipitating a dilute solution of subnitrate of bismuth in a very dilute alkaline solution, and dispensing the same in the form of minutely divided suspension. This minute state of subdivision gave cream of bismuth enormous spreading power, as could readily be demonstrated by administering it to a rabbit or other animal and then examining the intestinal mucosa with a microscope. Therapeutically its effects were superior to the bismuth salts as usually dispensed, the reason therefor being readily demonstrated by a similar test. Magnesium sulphate had been referred to. It might interest those present to know that a patent was granted early in 1917 for flavoring Epsom salt with aromatics. The report of the committee on patent-law revision of the A. M. A. so stated.

Dr. Henry Beates of Philadelphia stated he would like to quote from that too little known and valuable brochure of Harrington Sainsbury entitled "Principia Therapeutica," which so tersely explained the relationship existing between the circulation through the myocardium and the arterial blood pressure, and this, again, as related to the vitality of the patient. "Let us suppose a case of heart failure, no matter its cause, in which the left ventricle is unequal to its task, and, in consequence, the blood pressure is low in the ill filled arteries, the capillary stream sluggish and the great systemic veins congested. To attack such a problem as this with digitalis, a drug which by causing contraction of the arterioles sets up a new impediment to the already overburdened ventricle, this, at first sight, would appear to be the veriest midsummer madness; yet this very thing we do, and do again with *great success*. In explanation let us observe the steps which follow upon the administration of this drug. First, the arterioles contract and the blood, gathering behind the obstruction, begins to distend the arteries; the arterial distension is immediately followed by an increased gathering of blood within the ventricle, the pressure here rises and the heart muscle, responding to the stretch of its fibers by a more vigorous contraction, expels a large volume of blood into the aorta. We have, in fact, then, made a further call upon our already enfeebled heart, and its impoverished reserve stores are by so much the poorer. But observe what now happens. The increased volume of blood thrown into the aorta causes a corresponding rise in the aortic blood pressure, and on this there follows a more forcible recoil upon the semilunar valves and in fuller stream the blood enters the coronaries. Accordingly the first capillaries to feel the effects of the blood pressure rise are those of the heart-muscle itself. The improved circulation through its fibers raises its vigor and the heart, repaid now for its recent exertion, is prepared to respond to the stimulus of an increased intraventricular pressure by another more vigorous contraction. Slowly the whole aspect of the case changes: the arteries become well filled, the pulse more regular, forceful and measured, the capillary circulation freer and more sustained, the venous system less gorged. This is no question of theory or of interpretation, it is a sequence of events daily witnessed, not to be denied; neither is there any need to dispute the facts; for as we follow step by step this sequence the seeming therapeutic paradox that the proper treatment for a failing heart is to increase its burden, finds its simple explanation." Should the myocardial and arterial retrograde changes be such as to be beyond restoration the above phenomena would be impossible; again, should the vital unit with which the patient was born be almost spent, recuperative processes could not be activated. The practical point of vital import was to treat apparently hopeless conditions upon the principle of the Harrington Sainsbury therapeutic paradox, because experience proved that very frequently, where success was believed impossible, the test proved to the contrary. In this connection it would be well to bear in mind an histological fact too frequently overlooked, to wit: cells of all structure, excepting the splenic corpuscles and some perivascular lymph spaces of the central nervous system were not in direct contact with the blood. They were bathed with intercellular fluid, metabolism and functions were conditioned upon the normality of this intercellular fluid and the normality upon a mean pressure existing between the arterial side of the circulation on the one hand and the venous on the other. The fundamental principle to be applied in circulatory disturbances was therefore to be utilized in the treatment of metabolic and nutritional diseases as well as myocardial.

Dr. Zueblin said that for a final conclusion regarding ouabain medication a study of a great number of cases was required. He would not claim that ouabain would always help. It was one of the remedies that should be at hand in emergencies. It should be judiciously tried, but not repeated too often. It should be followed up by another medication—perhaps digitalis, perhaps strophanthus. Dr. Cornwell recommended the use of smaller doses of strophanthus. There was evidence that small doses of an active drug produced better results than large doses of an old preparation. In his observation the ionic properties of drugs had a great bearing upon therapeutic efficiency, and a great deal of information ought to be dug out by further experimental studies dealing with colloid chemistry and its relation to cell function. A better knowledge of these relations would be a help in therapeutic efficiency and an asset to the medical profession.

Dr. Andrew McFarlane of Albany, N. Y., said that his work was very superficial. It was impossible to get the work done with the thoroughness desired, as the laboratories in the camps were crowded to the utmost. In the South there were so many hundreds of examinations to be made for hookworm and tubercle bacilli. He tried to make some inquiries as to gastric capacity and defecation, but as far as answers went these things seemed to be normal. In presenting this subject it was not easy to make the necessary tests. In regard to high blood pressure, he thought that in man and in woman this was an entirely different proposition. What caused the high blood pressure? In man, toxic elements played a larger part. A woman might have a blood pressure of 200 and go on living quite comfortably. In man, he had often tried to reduce high blood pressure, but sometimes without result. Venesection had been found a satisfactory method. This could be done easily and satisfactorily with the aspirator. It made no mess with the blood, which usually so frightened the family, and by inserting the needle into the vein 12 to 14 ounces of blood could be withdrawn with no trouble, and no sign of bloodshed. One could tell exactly how much blood was removed. Rest should include physical rest, dietetic, and mental rest. There should be a therapeutic compromise between rest and exercise. It was a very wise man who knew just how to balance these two necessities.

Dr. Bishop said that his paper was merely suggestive. He had not tried ipecac alone, but always in combination with digitalis. In regard to Dr. McFarlane's paper, as a member of the Advisory Board he was interested in the special rôle of the heart. He had been impressed by this type of patient. When looking for the left ventricle they did not seem to have any. In the electrocardiogram these patients' hearts were relatively right-sided. They represented a heart that was a reversion to the infantile type. When the child was born there was no left-sided preponderance. In the first few hours of life the left ventricle came into its own. He did not know how to classify this type of individual. Dr. Mackenzie had spoken of their having "x-disease." They had the disease that the specialist they went to happened to treat. They showed cold cyanosed extremities, a systolic sound, and when fluoroscoped the heart was found in the middle of the chest, like congenital heart cases. One could not convict these people with heart disease; as far as the heart was concerned they might go on with their work. Some few of them were definitely congenital heart cases, with moderate pulmonary stenosis, possibly open foramen ovale. But the type certainly presented reversion to infantile characteristics. One thing that stood out in the speaker's mind after taking thousands of polygrams and hundreds of electrocardiograms, these arrhythmias were not distinct entities, but merged one into the

other. People started with palpitation, later they had flutter, and they might go on to fibrillation. The underlying cause was probably one and the same. It was no doubt toxicity. As to diet, it seemed that the heart was an engine that ran by the explosion of food. Like the gas engine, the best fuel for it was the one that left least waste to be cleaned up. It would seem then that the lactovegetarian diet best fulfilled this condition. In regard to fuel, a very observing Englishman had cured a great many cases by stoking them up with cane sugar. Dr. Bishop had a patient last winter, at Newark, a very obese woman, who had tried a reduction cure, and her heart was down and out. The Newark doctor telephoned one day to say she was in an extreme condition. The idea came to his mind to suggest the use of cane sugar. This was tried, and the patient immediately got better. He could not say whether this was a random shot, or whether there really was a good deal in the theory. The best food, it would seem, would be the one to burn with least residue, and if instant energy were required it would seem that cane suger filled the requirement. Old people did not need to have their structures built up, and so the proteins were not required. A carbohydrate diet would seem to be sufficient. As to the question of rest and exercise, he did not do anything but consultation work, and he did not therefore observe people in bed for a long time. He had to prescribe what exercise was needed. Sometimes he had the pleasure of liberating people from unnecessary confinement, but sometimes he had to advise the opposite thing. In regard to the electrocardiograph, it was an autograph of the heart's action. He did not believe that the intricate interpretation of these things was necessary, but he did think that the profession needed to learn more or less what was shown. He was beginning to collect these tracings, with the idea of teaching the profession what these things looked like and what they indicated. Many men at medical societies, when shown these things, took them in their hands upside down.

Dr. SATTERTHWAITE said that rest and exercise were both essential. In children, especially in endocarditis, to get a satisfactory cure they had to rest in bed. That rest might be for two or three weeks, or for as many months. Another condition requiring complete rest was fibrillation or flutter. One could not control it without putting the patient to bed. Rest in the horizontal position was essential. Exercise was just as necessary in some chronic cases. The Nauheim cure commenced with passive exercise and graduated walking distances. Keeping the patients too long in bed put them back. After a while it became necessary to get out and take moderate exercise. In regard to "irritable heart," the society owed a debt to Major McFarlane for his talk. Da Costa, in the Civil War, used this term until Sir Thomas Lewis changed the term to "effort syndrome." This emphasized the idea that there existed a muscular weakness, but he thought that Major McFarlane's term carried out the idea further; he had called it neurocirculatory myasthenia. That was a distinct progress. One should, however, regard Sir Thomas Lewis as the foremost exponent of the physiological action of the heart. The cure was effectively graduated exercise. There was a neurotic element behind all these cases. The introduction of the adjective "neuro" into the term was illustrative of the condition. There might be something more behind that, but the neurotic element was certain. In reference to diet, they would agree with Dr. Cornwall that in acute infection or acute exacerbation of heart disease one should limit the diet to milk for several days, followed by a more liberal diet. The general diet had to be studied according to the individual requirements; one could not lay down hard and fast rules. The diet must be restricted, the stomach must not be overloaded, food must be satisfying and yet not heavy. In regard to the use of morphine, he had never employed it, having had success with the use of bromides and veronal. He felt a fear of using morphine. It did the work, but it had the danger of habit-forming. The physician should reasonably fear to have the charge of habit formation laid up against him in these chronic cases. Dr. Vander Hoof had said that one was often disturbed by the irregularity of the heart in boys and girls. In sinus arrythmia the heart was extremely irregular, weak, and changing in character. This was a frequent condition of growing youth. It required no treatment except regulation of manner of life and general hygiene. People were unnecessarily alarmed, but the condition was transient. As to high blood pressure, this question had become a nightmare. Patients came one day with a pressure of 200; without any change, another day showed it to be 150, then 180, then 140. There was a neurotic element in such cases, but a good deal of study had to be done on that as yet. Many people had cerebral hemorrhage with a low pressure. Insurance men required a pressure of 28 to 30 diastolic. Doctors never saw that; they saw 60 to 80. One did not know that a low pressure was normal in diseased conditions, and it had not been worked out what the average blood pressure should be in tuberculosis or uremia or diabetes, for instance. While they knew the normal, they did not know what it should be in disease. People did fairly well for a long time with high blood pressure. In reference to the shadow of the heart shown in the skiagram, Dr. Hirsch claimed that it was due to the vibrating of the heart and dilatation of the right auricle. That was the interpretation of the *x*-ray man. Dr. Satterthwaite was not absolutely convinced that they were getting skiagrams of actual auricular disease.

Papers Read by Title.—"Modern Therapeutics in the New York State Hospitals for the Insane," by Spencer L. Dawes of New York; "A New Case of Uterine Rheumatism and Its Management," by William A. Porter of New York; "Phenylcinchoninic Acid," by Reynold Webb Wilcox of New York; "The Physiological Chemistry of the Duodenal Contents in Cholelithiasis," by John C. Hemmeter of Baltimore.

Election of Officers.—The following officers were elected: *President*, Dr. Douglas Vander Hoof, Richmond, Va.; *First Vice-President*, Dr. Harry B. Anderson, Toronto, Canada; *Second Vice-President*, Dr. Thomas E. Reilley, New York City; *Third Vice-President*, Dr. C. F. E. Mattison, Pasadena, Cal.; *Secretary*, Dr. Lewis H. Taylor, Washington, D. C.; *Treasurer*, Dr. Spencer L. Dawes, New York City. *Council*, Drs. Noble P. Barnes (1921), chairman; Robert T. Morris (1921), vice-chairman; Lewis H. Taylor (1923), secretary; Thos. E. Satterthwaite (1919), John Blake White (1919), G. H. Evans (1919), Wm. A. Campbell (1920), W. Wayne Babcock (1920), F. M. Pottenger (1920), Jacob Diner (1921), A. D. Blackader (1922), C. E. Jennings (1922), J. N. Hall (1922), S. L. Dawes (1923), Stuart McGuire (1923). *Committee on Admissions*, Drs. Satterthwaite, Pottenger, and Jennings. *Editor of Transactions*, Jacob Diner, New York City.

SECTION ON MEDICINE.

Stated Meeting, Held May 21, 1918.

DR. SAMUEL A. BROWN IN THE CHAIR.

Neurological Phenomena in Cardiovascular Diseases.—Dr. H. CLIMENKO presented this paper. (See page 366.)

Organic Nervous Manifestations in the Course of Diseases of the Blood and Blood Forming Organs.—Dr. I. ABRAHAMSON presented this paper, in which he said that the structural changes in the nervous system which accompanied severe anemia, pernicious anemia, leucemia and chloroma, Hodgkin's disease, grave malaria, pellagra, polycythemia vera, Addison's disease, general carcinosis, tuberculosis, diabetes, lues, lead and ergot poisoning, all resembled one another so strikingly that one could distinguish a definite group picture characteristic of the nervous system in these blood conditions. The structural changes which most frequently occurred in this group were multiple hemorrhages and myelitic foci surrounded with infiltrated areas. Thus a diffuse myelitis, mainly in the dorsal region, was produced which was accompanied by a secondary degeneration, affecting the posterior columns, pyramidal tracts, Clarke's columns, Flechig's and Gower's tracts. This morbid change was commonly called subacute combined sclerosis. The essayist, after reviewing the various theories which have been advanced regarding the way in which the disease was spread,

stated that Nonne's theory was the one most widely accepted today. Nonne ascribed all the changes to a funicular myelitis and pointed to the significant fact that the disease of the roots rarely extended beyond the cord proper and that only the intra-spinal portions of the roots were implicated. The degree of anemia seldom corresponded with the degree of nerve destruction. The nerve changes might not merely persist, they might increase in severity concomitantly with the amelioration of the anemia. Experimentally induced anemias such as that following the injection of lycopodion powder were not, as a rule, accompanied by any nerve lesions. In uncomplicated chronic anemias the occurrence of structural changes in the nervous system was so rare as to be doubtful. The exciting cause of the structural change in the nervous system in blood disease was therefore not the anemia *per se* but an accompanying toxemia. In the anemia accompanying the *Bothriocephalus latus* infection the nerve changes were of frequent occurrence and the toxin which produced them had actually been isolated. The toxin produced relatively slight anemia but relatively grave nervous changes. In discussing the symptomatology, the essayist said there was no distinct parallelism between the extent of the nerve lesions and the severity of the symptoms that arose from them. With slight lesions grave symptoms might exist; with few symptoms the nerve tissues might be invaded to a surprising extent. This seeming anomaly depended in part on the rate of development of the lesions, partly upon the compensatory activity of the unimpaired portions of the nervous system, and partly upon the psychic reaction to the structural alterations. A similar discrepancy between symptoms and lesions might also be often seen in tabes and in multiple sclerosis. The extent to which the nervous system was implicated depended upon the stage of the disease; at the onset the localized irritability alone might exist; later the invasion spread and the manifestations of the disease become more pronounced, until finally widespread paralysis might result. The nature of the manifestations varied with the essential site. The signs of motor column degeneration were chiefly atony, loss of tendon reflexes, and ataxia, and loss of the deep muscle reflexes. The signs of pyramidal tract involvement were motor weakness, hypertonia, and exaggerated deep reflexes. These signs might be found in all possible combinations, depending upon the degree to which each of these columnar systems was respectively implicated. In addition, pains and paresthesias and objective sensory disturbances were usually present. Rarely optic atrophy occurred and still more rarely pupillary disturbance. Under the title, subacute ataxic paraplegia, Risien Russell, Batten, and Collier gave a very comprehensive study of this syndrome. The disease lasted from six to eighteen months. It could be differentiated into three stages: (1) That of paresthesia, pain, mild spasticity, and ataxia. (2) That of definite spastic paraplegia with objective sensory disturbances in the trunk and legs. (3) That of flaccid paraplegia, loss of tendon reflexes, complete level anesthesia, loss of sphincter control, general and local muscular wasting, electrical changes in the muscles and nerves, girdle sensation, herpes zoster, disturbance of pain and temperature sense, edema, and trophic skin disorders. With these marked mental symptoms occurred confusion and disorientation, and apathy and coma. The prognosis in general was very unfavorable; the progress of the disease, however, might be slow and characterized by remissions. A few cases of apparent recovery were recorded. The disease thus described was that characteristically met with in the nervous system as an accompaniment to most blood affections. The writer also directed attention to a less well-known structural alteration of the nervous system which was sometimes seen in Hodgkin's disease, in leucemia, and in chloroma. In these conditions foci of dense infiltration with lymphocystes might occur in the meninges, along the nerve roots in the cord itself, and in the vertebræ. Such cellular infiltrations superadded to the picture outlined gave the symptoms of a transverse myelitis, either of intraspinal origin or actually secondary to compression of the cord by meningeal or extraspinal accumulations. Hence a syndrome was produced which needed to be very carefully distinguished from Pott's disease and from tumors of the cord. From a large number of cases which the essayist had encountered he selected the following as specially illustrative of the diseases of the nervous system which accompanied blood affections: (1) Severe secondary anemia with myelitis. (3) Pernicious anemia in a luetic with a clinical picture of tabes. (3) Hodgkin's disease presenting a tabetic picture with no evidence of lues. (4) Polycythemia vera showing affection of the nervous system.

Tuberculosis of the Stomach, with Report of a Case of Multiple Miliary Tubercles.—Dr. GEDIDE A. FRIEDMAN read this paper, in which he stated that tuberculosis of the stomach was a very rare condition. A report from the Mayo clinic showed in a series of 2,501 gastric operations but one instance of tuberculosis of the stomach. Gastric tuberculosis might be divided into six types, as follows: (1) ulcer (single or multiple), (2) miliary tubercule, (3) solitary tubercle, (4) pyloric stenosis, (5) tumor nodule (single or multiple), and (6) lymphangitis. In the ulcer type there was no difference between the gross and microscopical appearance of the tuberculous gastric ulcer and the tuberculous intestinal ulcer. Both might be associated with miliary tubercles. Miliary tuberculosis of the stomach was usually associated with general miliary tuberculosis. The solitary tubercle was very rare. Tuberculous stenosis of the pylorus was of two types, the true and the false. The true type included the cases in which the pylorus was obstructed by an old tuberculous ulcer, with an excessive amount of scar tissue and tuberculous granulations, or by a diffuse and non-ulcerative tuberculosis of the pylorus. In the false type, the stenosis was brought about by enlarged tuberculous peripyloric lymph glands, or by tuberculous peritonitis in the region of the pylorus, accompanied by adhesions, often involving other organs in the process. Tumor or nodule and lymphangitis were very rare conditions. The mode of infection of the stomach might be through the mucosa, the blood stream, the lymphatic system, and by continuity or contiguity of structure. There seemed to be a relative immunity to tuberculous gastric ulcer. Arloing was able to produce experimentally only one ulcer in the stomach and one in the duodenum, both times in dogs. The rarity of gastric ulcer was ascribed to the sparsity of the lymphatic supply of the gastric wall and by Kleber to the same cause, and also to the deep-seated location of the lymph follicles. Of 306 cases reported in the literature, 157 were positive or probable cases of gastric tuberculosis and the remainder Broder considered doubtful or rejected altogether. The cases were considered positive that contained a histological picture, and in addition the presence of the bacillus of tuberculosis in the depths of the lesion or the presence of the specific bacillus in the depths of an indefinite histological lesion. He considered as probable all cases that possessed a histological picture of tuberculosis. Of these 157 cases, 108 occurred in adult, 35 in children, and in 24 the age was not indicated. Eighty-nine occurred in males and 48 in females, while in 30 cases the sex was not indicated. The tuberculous process in the stomach was considered primary by several writers, but the consensus of opinion was that no case should be considered primary unless a thorough search failed to show any evidence of the disease in any other part of the body. The case which the speaker reported occurred in a woman, twenty years of age, a clerk, who was admitted to his service at the Beth Israel Hospital on February 21, 1918, complaining of pain in the epigastrium and precordial region, vomiting, headache, loss of weight, weakness, and constipation. The father and two sisters had stomach trouble; otherwise the family history was negative. The patient had had the usual diseases of childhood and had been anemic in early childhood. The history of her present illness covered four months. She had never noticed any blood in the stools nor were they at any time tarry. Physical examination revealed nothing except a high arched palate, slight prominence of the thyroid, fairly marked rigidity of the abdomen, tenderness in the upper left quadrant, and exaggerated knee jerks. The laboratory findings were as follows: Blood examination showed erythrocytes, 4,800,000; leucocytes, 12.000; hemoglobin, 85 per cent.; polymorphonuclears, 69 per cent., and lymphocytes, 31 per cent. The urine was practically normal. The stomach con-

tents, after a test breakfast, showed total acidity, 56; free hydrochloric acid, 18; no blood. The *x*-ray examination showed an ulcer at the lesser curvature with adhesions. The patient was operated on by Dr. A. O. Wilensky on March 5, 1918. At the operation an area of the lesser curvature about two inches long, extending along the anterior and posterior surface of the stomach for an equal distance, was thickened and inflamed. There were numerous fresh fibrinous adhesions and large numbers of miliary tubercles were thickly scattered in the inflamed area. The process extended upward into the gastrohepatic omentum for about one inch. The gross diagnosis was tuberculosis. The rest of the abdomen was explored and no other focus of tuberculosis found. The pathological report showed caseation of the tubercle and giant cells and nuclei. The patient made a good recovery and showed no evidence of tuberculosis elsewhere in the body. The von Pirquet and the complement fixation tests were positive, that latter being weakly so.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

SECTION ON INDUSTRIAL MEDICINE AND PUBLIC HEALTH.

Stated Meeting, Wednesday, May 15, 1918.

DR. JAMES M. ANDERS IN THE CHAIR.

Hazards of Metal Mining.—Dr. A. J. LANZA, U. S. P. H. S., Pittsburgh, Pa., pointed out that metal mining in contradistinction to coal mining has always been recognized as hazardous to health. Moreover, metal mining had contributed to medical science an occupation disease of the first magnitude, the socalled miners' consumption, not confined, however, to the miner. Miners' consumption—silicosis—he said was a pneumonoconiosis caused by the inhalation of silicious dust. It was among hard rock miners, however that it had become the scourge of mining camps. Hippocrates had spoken of "the metal digger who breathes with difficulty and is of pale complexion." From 20 to 35 per cent. of hard rock miners were said to be affected, a condition taking precedence over any other occupational disease. Individual susceptibility played little part. The amount of silica in the dust, the duration of exposure, and the intensity of work were the determining factors. The cardinal symptoms of silicosis were given as dyspnœa on exertion, pain in the chest associated with diminished expansion. The dyspnœa appeared insidiously in from two to ten years and grew gradually worse until total disability might result. This might be the only symptom. Pain in the chest became definitely located and there was generally a bronchitis with cough; in some cases cough was not present. Loss of weight was said to be not as great as in tuberculosis. Aside from their dyspnœa, the patients felt and looked well; they had no fever, or nightsweats; hemorrhage was occasionally present. Physical examination showed little except in advanced cases. At any stage of a silicosis tubercular infection might occur and this usually ran a fairly rapid course. In Joplin, where the type of silicosis was very severe, tubercle bacilli practically always appeared in the sputum before death. In Butte, where the condition was not of such an aggravated type, tubercle infection was not so frequent. The prognosis was said to be bad after silicosis was well established; and when tubercular infection had occurred the prognosis was usually hopeless. An outdoor life seemed to afford the only chance for recovery in early cases. In the pathology of the disease there was first a peribronchial thickening followed by small nodular fibrous areas tending to coalesce in dense fibrous areas which might undergo anemic necrosis. The relation of the tubercle bacillus to this process was not clear. Inability to obtain necropsies prevented study of this feature. It has been shown that dust particles lodging in the lungs were not larger than from two to five microns, and even smaller. The prevention of the disease lay in the use of water in drilling, a matter not always as simple as it would appear to be. It was evident from the small size of the dust particles that the use of respirators was futile.

Dr. HENRY K. PANCOAST referred to his privilege of having interpreted for Dr. Lanza about fifty pairs of stereoscopic plates made among the hard rock miners at Butte, Montana. A great similarity was noted in the appearance of these plates and those made in connection with the investigations of Drs. Landis, Miller, and Smyth, and himself, in dusty occupations in the eastern part of the country. The Roentgen ray he regarded as the most accurate method of determining the condition of the lung in the living subject. Authors were practically agreed upon the interpretation of the *x*-ray plates in pneumonoconiosis. There were said to be three stages. In the first the appearance was that of an enlargement of the hilus shadow and an increase in the thickness of the linear markings. The age of the patient and place of residence were to be considered; those living in large cities were apt to have more or less evidence of pneumonoconiosis with advance in years. In the second stage there was mottling in the parenchyma of the lung, due to small deposits of dust and and associated circumscribed fibrosis. These spots gradually enlarged and finally coalesced. In the third stage there was a diffuse fibrosis which selected certain portions of the lungs and seemed to originate from a coalescence of the small areas mentioned. There appeared to be certain anatomical distributions for the mottling and the diffuse fibrosis; the findings in this connection had been fairly uniform, both in Dr. Lanza's plates and in those of Dr. Pancoast and his confreres. In the appearance of the second stage the mottling began especially around the root of the lung and in most cases there was greater progress on the right side. The mottling then spread around the lung from base to apex. In the plates examined for Dr. Lanza the most intense mottling was a little above the center of the lung from the second to the fourth interspace, and in this region most of the diffuse fibrosis was to be seen in the older cases. In some of the more advanced second-stage cases it was often most difficult to find very marked enlargement of the hilus shadow or thickening of the bronchial trunk shadows. This was true also of the third-stage cases. Of this *x*-ray workers had at the present time no explanation. It seemed as though some of the cases progressed rapidly in the second stage, while others remained in the first stage for a long period of time. Fluoroscopic examinations were always valuable in this study and explained in large measure the difficult breathing. In some instances the diaphragm seemed not to move owing to the fibrosed condition of the lungs, particularly in a line with the linear trunk shadows running to the bases. The real cause was without doubt an inability of the lung to expand. In some cases the inner portion of the diaphragm was fixed, whereas the outer portion moved to a certain extent and seemed to be hinged at the point of contact of the linear trunk shadows.

Dr. H. R. M. LANDIS observed that the cases studied by Dr. Lanza in Joplin, so far as he knew, presented the most serious cases of silicosis, even outranking those of South Africa. The *x*-rays had done much in discriminating between dusts entirely harmless, in the sense of producing no definite pathological changes in the lungs, and those causing serious and crippling lesions. They differentiated the effects produced by the organic and the inorganic dusts. At one end of the scale there were to be observed pure silicosis, which of itself and entirely aside from any secondary tuberculous lesion was sufficient to cause absolute incapacity. There were other forms of inorganic dust, however, exposure to which did not prevent workers from being able to follow their trade for from forty to sixty years. In one instance a potter who had been apprenticed when a boy of ten had worked at the trade until he was seventy. The effect of the concentration of the dust was well shown in the slides exhibited by Dr. Pancoast. One showed the lungs of a man who had been working in a coal mine for thirty-two years; another had worked outside on a breaker for thirty-eight years. While there was much dust in the work on the breaker, being outside there was not the same concentration as in the mine. In the case of the man working outside for thirty-eight years, there was probably not one-quarter of the pulmonary change shown in the man working for thirty-two years underground. The only explanation Dr. Landis could offer of the susceptibility to tuberculosis of the cases studied at Joplin was that the condition was so very acute *x*-ray workers had no

means of knowing whether the great irritation produced an acute inflammatory change rendering the tissues more susceptible to the tubercle bacillus. The sociological background referred to in Dr. Lanza's studies was an important feature. Furthermore, Dr. Landis stated that it was perfectly clear that without the tubercle bacillus there could be no tuberculosis. Tuberculosis and pneumonoconiosis were designated as distinct problems. The knowledge of pneumonoconiosis had been greatly increased by the use of the *x*-rays. As Dr. Pancoast had said, physical signs were absent or extremely indefinite in the first stage. In the advanced stage the ability to elicit marked physical signs was of no particular moment, so far as the patient was concerned, as the damage was already done.

Dr. Alfred Stengel said that the important question encountered was that of the management of the industries, in view of the war situation, with the unprecedented conditions presented. There was the matter of the excessive speeding up of industries, with a certain degree of carelessness which was being excused on the ground of war conditions. Sooner or later cognizance must be taken of this prevailing form of excuse. Fortunately the Government, through various agencies, was taking up the regulation of industries in this connection. The new industrial poisons, suddenly let loose and concerning which there had been until very recently the most inadequate knowledge, had occasioned many cases of illness and perhaps a considerable number of deaths. Physicians, apart from those few who happened to have special knowledge of industrial medicine, were not familiar with even the scanty literature which now existed upon this subject. Cases of apparently obscure illnesses, located at times some distance from the industrial plant, were very ordinary instances of industrial poisoning, perfectly plain to those experienced with them. He had had in his service at the University Hospital quite a number of cases of, to him, entirely new types of disease which would have been obscure had he not known of them through the literature. The probability of encountering such industrial disease should be realized by the medical profession. Dr. Stengel had heretofore suggested that there be instituted public meetings, which physicians should be encouraged to attend, at which an educational program might be enforced. It was not known, he said, how many hundred thousand in the industrial center of Philadelphia were exposed to fumes of the most intense poisons, who were in the habit of going from place to place, as mentioned by Dr. Patterson, and in each industrial plant having renewals of the poisoning so that the amount of incapacitation and death was a serious matter. He believed all medical schools had consented to incorporate in their curriculum definite courses of lectures, with examinations and tests, and to make it incumbent upon students to acquaint themselves with these diseases. This was one of the good things he remarked, that had come out of the stirring events of the present time.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Board of Medical Examiners of Maryland.

December, 1917.

(*Concluded from page* 310.)

OBSTETRICS AND GYNECOLOGY.

1. What changes occur in the breasts during pregnancy?
2. How can you predict the day of confinement?
3. Give some of the causes of abortion and premature labor.
4. In the case of twins, how can you tell from the placenta whether they are from the same ova or from different ones?
5. What is strictura uteri, and what is its treatment?
6. What are some of the dangers of precipitate labor?
7. What is the chief cause of hemorrhage prior to the time of labor, and what is your treatment for this condition?
8. Under what conditions would you do an internal podalic version, and describe in detail how you would perform it?
9. Give treatment of vaginitis of pregnancy.
10. Differentiate between a sloughing myoma and a cancer of the uterus.

SURGERY.

1. Give the differential diagnosis between acute catarrhal conjunctivitis and gonorrheal ophthalmia.
2. Give symptoms and treatment of acute catarrhal otitis media.
3. Give symptoms and treatment of tuberculosis of the hip joint.
4. What technique and treament would you employ for a gunshot wound of the leg?
5. What do you understand by a Colles fracture? Give signs, symptoms, and treatment.
6. What are the symptoms of a chronic luxation of a semilunar cartilage of the knee joint? Give treatment.
7. Describe rodent ulcers. Give their common locations and treatment.
8. Name the varieties of goitre and mention the indications for surgical interference.
9. What is the most frequent dislocation of the shoulder? Give diagnosis, two methods of induction, with after-treatment.
10. Give diagnostic characteristics of (*a*) varicose, (*b*) tuberculous, (*c*) luetic ulcer.

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. *During pregnancy* the mammary glands increase in size, fullness and firmness; Montgomery's follicles become pronounced; the primary areola becomes larger and darker; the secondary areola appears; the nipple becomes larger, more prominent and more erectile; and colostrum may be expressed.

2. *To predict the day of confinement*, it is customary to add seven days to the first day of the last menstrual period, and then count back three months. Sometimes this gives the exact date, and usually it is within a few days of the date.

3. *The causes of abortion and premature labor* may be briefly enumerated as follows: "(1) Any pathologic condition of the ovum, membranes, or placenta, such as apoplexies, cystic degeneration of the chorionic villi, and cellular infiltration of the placenta. (2) Certain general diseases of the mother, including syphilis, typhoid fever, the exanthemas, and conditions interfering with proper aeration of the blood, as pneumonia and valvular heart disease; various systemic poisons, as malaria, lead, and arsenic; certain blood diseases, as grave anemia and leukocythemia; various local conditions, such as metritis, salpingitis, and ovaritis, cystitis, appendicitis, and placenta prævia. (3) Diseases of the father, such as syphilis, phthisis, and nephritis, in which the spermatozoa are diseased or of lessened vitality. (4) Death of the fetus from any cause. (5) Traumatism, as from a fall, a blow, or a kick on the abdomen. (6) Spasmodic muscular action, as in chorea, uncontrollable vomiting or coughing, convulsions of any kind. (7) Reflex causes, as violent emotion or mental shock. When the uterus shows a tendency to contract under the slightest stimulus (irritable uterus), any trivial cause, such as a long walk, a hot bath, or even the sight of another woman in labor may result in abortion. (8) Criminal abortion, caused by the use of drugs, vaginal and uterine injections, and the introduction of an instrument into the uterus."—(*Pocket Cyclopedia.*)

4. If the twins are from two ova, two placentæ may be expected; if from one ovum, one placenta may be expected. But in the former case there may be fusion of two placentæ.

5. *Stenosis of the cervix* may be congenital or acquired. The latter may be due to uterine displacements, inflammations of the cervix, contraction after labor, or to operations such as amputation or the frequent application of strong caustics to the cervix. *Treatment* consists in dilating the cervix and curing any local condition that may be present (such as endometritis). Incision is often advisable with the dilatation. For the dilatation, the patient is placed in the lithotomy posi-

tion and anesthetized; the cervix is pulled down with a volsella, and the canal enlarged with a series of Hegar's dilators, or a Sims' dilator.

6. *Dangers of precipitate labor:* Lacerations, premature detachment of placenta, rupture of the umbilical cord, postpartum hemorrhage, syncope, inversion of the uterus, shock, asphyxiation of the fetus.

7. *Severe ante partum hemorrhage* is most likely to be due to (1) accidental hemorrhage, due to premature separation of the placenta; (2) to placenta prævia.

The treatment is practically the same in each case, namely, to check the hemorrhage and promote delivery. In *accidental hemorrhage* the membranes should be ruptured and the vagina packed, or *accouchement forcé* performed; vaginal cesarean section has been employed. In *placenta prævia:* (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child.

8. The *indications for podalic version* are: (1) In transverse presentations; (2) in placenta prævia; (3) in malpresentations of the head; (4) in simple flattened pelvis, and in minor degrees of pelvic contraction; (5) in prolapsed funis; (6) in sudden death of the mother; and (7) in any case where speedy delivery is imperative.

"*Internal version* is done by passing one hand into the uterus, seizing and bringing down one or both feet. The cervix must be sufficiently dilated to allow the hand to pass. It should be done as soon as possible after the membranes have ruptured. If there is only slight retraction of the uterus it may be done, by an expert operator, by deeply anesthetizing the patient, but one who has not had much experience of the operation should not attempt it. If the uterus is firmly retracted it should never be attempted. The patient may lie on her left side, or preferably on her back. The right hand may be used in all cases, but in some the left one does better. It depends on which way the child is lying. Use the hand which will most easily reach the front of the child. Thus, if its back is toward the mother's right side, use your right hand, and if the back is toward her left, the left hand; but if you are not accustomed to working with your left hand always use the right. The hands and arms should be thoroughly sterilized, and well washed in lysol solution. Pass the hand in a cone shape to dilate the cervix, if it is not sufficiently dilated already, and pass the hand on to the front of the child, rupturing the membranes, if they are unruptured. As much of the liquor amnii as possible should be retained in the uterus by damming it back with the wrist. If a contraction comes on, spread your hand flat on the front of the child and wait until the uterus relaxes. If you do not do this the pressure upon your closed hand will almost paralyze it, and may cause rupture of the uterine wall. Catch one or both feet, making sure it is a foot and not a hand. As soon as you get a foot, pull the leg down steadily into the vagina, if the uterus is quiescent, but if a contraction comes on, wait, spreading your hand out as before. The child's body usually rotates quite easily, unless the uterus is retracted around it. If version is attempted when the uterus is retracted, as in a transverse case, care must be taken to unhitch the shoulder from under Bandl's ring, if it is caught, but only an expert should undertake such a risky operation, and it should only be undertaken if there is a chance of saving the child's life. The final part of the delivery is carried out in exactly the same way as when the breech presents."—(Jardine's *Delayed and Complicated Labor.*)

9. If the *vaginitis* is *non-specific*, the vulva and vagina should be bathed daily with warm antiseptic lotions. In the *gonorrheal* type, vaginal douches of mercuric chloride (1:3000) or potassium permanganate should be administered twice daily, and a tampon with glycerol of tampon should be inserted. Application of a 1 per cent. solution of lactic acid to the vaginal walls has been advised.

10. The following table of differential diagnoses is given in Dudley's *Gynecology:*

ADVANCED CARCINOMA OF UTERUS.	SLOUGING SUBMUCOUS MYOMA.
1. Cachexia, hemorrhage, and very foul discharges.	1. Anemia from hemorrhages; discharges less foul.
2. Sloughing tissues very friable.	2. Tough, not friable.
3. Cervix may be involved by extension.	3. Cervix not so involved.
4. Characteristic epithelial proliferations seen by microscope.	4. Absent.

SURGERY.

1. In *acute catarrhal conjunctivitis:* "Patients complain of stiffness of the lids, photophobia, epiphora, burning, and sensations of a foreign body. There is no actual pain, but considerable discomfort, especially in the evening. The lids are swollen and red. The conjunctiva of the globe is more or less deeply congested, and that of the lid is thickened, congested, and rough. Occasionally there are subconjunctival hemorrhages. The mucopurulent discharge is collected at the roots of the lashes or lies on the surface of the conjunctiva. The lids are stuck together in the morning. The vision is only slightly affected by the mucous discharge on the surface of the cornea, which is otherwise clear, although minute ulcerations of the cornea are occasionally seen."

In *gonorrheal conjunctivitis.*—"The patient, who generally has a gonorrheal urethritis, presents himself with great swelling and tension of the eyelids, more or less purulent discharge escaping between the lids. The conjunctiva is swollen and thickened. There is little pain but great discomfort. The cornea soon shows infiltration, and ulcers form. These perforate, leading to destruction of the eye or at best deep corneal opacities."—(From *Epitome of Eye and Ear.*)

2. *Acute catarrhal otitis media* is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops, warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

3. TUBERCULOSIS OF THE HIP JOINT.—"There are three stages of the disease: (1) That which extends from the beginning to the development of pus in the joint, and is characterized by localization of the disease, flexion, limping, pain, usually referred to the knee, slight induration about the joint, fixation and atrophy of the muscles, and enlargement of the neighboring glands. (2) The stage that extends from the end of the first stage until the development of pus outside of the joint, or the stage of joint involvement, and is characterized by abduction and apparent elongation, night cries, abscesses, joint crepitation, and failure of the general health, in addition to the symptoms of the first stage intensified. (3) The stage that extends from the end of the second stage to the termination of the disease or the stage of destruction of the capsule and external suppuration. Adduction, flexion and real shortening are present, and dislocation and ankylosis or suppuration, destruction of the joint, asthenic symptoms, and death result.

"*Treatment:* In the early stages the patient must be kept in bed, with a weight extension applied in the line which the thigh takes, and as the flexion disappears, the pulley is lowered. When the pain has disappeared and the limb is horizontal, the patient can get about with a Thomas's hip-splint, a patten on the sound leg, and a

pair of crutches. These must be worn for at least six months after symptoms have disappeared. The general health must be attended to by good feeding, sunshine, and fresh air. Phelps' box is a useful apparatus in this stage. If abscesses form, they should be opened, scraped out with a flushing spoon, and stitched up. Excision of the head of the femur and free scraping out of the joint by the anterior incision is sometimes done in the early stage; but much shortening and a weak, movable joint are the results, while complete removal of all the diseased tissues is difficult. However, excision should be done where the disease progresses in spite of treatment, and where the disease is primarily acetabular. In the *late stages*, where septic sinuses are present, the head of the femur should be excised by the posterior incision, diseased bone removed from the acetabulum, and the tuberculous synovial membrane completely dissected away. Amputation is required if the disease still progresses, if amyloid disease has commenced, or if the patient's general health is too low to stand a prolonged operation."—(*Aids to Surgery.*)

4. "The treatment of gunshot wounds is conducted in accordance with general surgical principles, although it may have to be somewhat modified by the patient's environment and by the fact that after a battle the pressure of work may be such that all lengthy operative procedures have to be discarded. The first essential is to protect the wound from infection, and for this purpose the small packet of antiseptic dressing carried by all soldiers is admirable. Bleeding is controlled by a tourniquet, and splints must be improvised for broken limbs. As soon as the wounded man reaches the field hospital, the wound is more thoroughly explored and cleansed; foreign bodies are removed, bleeding-points secured, and if the bullet has not escaped and can be readily detected, it should be extracted. When lodged deeply, its position may be determined by skiagraphy, or by such appliances as Nélaton's porcelain-ended probe, or more complicated electrical contrivances, such as the telephone probe. Comminuted fractures are carefully investigated, detached fragments of bone are removed, and if an attempt is made to save the limb, splints, etc., are carefully applied. Primary amputations for bullet wounds are not very common at the present day, except when great comminution of bone or hopeless involvement of vessels and nerves has occurred."—(Rose and Carless' *Surgery*).

5. *Colles' fracture* is a transverse fracture at lower end of radius; it is due to falls on the outstretched palm. The line of fracture is about an inch above the wrist, and runs obliquely downwards from behind. The lower fragment is driven backwards and upwards, and rotated to the radial side, carrying the hand with it into the position of abduction, and leaving the tip of the radius at the same level as, or higher than, the tip of the styloid process of the ulna. The internal lateral ligament of the wrist is ruptured or the styloid process torn off. The fracture is usually impacted, the upper fragment being driven into the lower. The deformity is characteristic, viz.: (1) the hand is abducted; (2) the styloid process is on the same level as, or lower than, the tip of the radius; (3) the upper end of the lower fragment projects above the back of the wrist; on the front is a corresponding depression, while above it the upper fragment projects forward. Union occurs readily, but it is common to get deformity and adhesions about the site of fracture. *Treatment:* Disimpaction and reduction are brought about by grasping the hand by the "shaking-hands" grip, extending and adducting the hand and lower fragment. The arm is then fixed on a splint. It is very important in this fracture to start massage and passive movement not later than the end of the first week, to prevent stiffness. Union is firm in three weeks.—(*Aids to Surgery*).

6. Luxation of Semilunar Cartilage of Knee.—*Symptoms:* "Violent pain in the knee joint, chiefly on the inner side over the lateral ligament. The knee is locked in a semi-flexed position. Synovial effusion with its usual signs appears within a few hours. Later, and in the absence of proper treatment, recurrent attacks of synovitis often occur in any action of flexion and rotation of the knee. Tenderness is most marked on pressure over the tibial attachment of the internal lateral ligament. Very rarely a lump or gap can be felt in the position of the cartilage."—(Grove's *Synopsis of Surgery.*)

Treatment: "Reduction by flexion and extension of the joint. Immobilization on a back-splint for six weeks, followed by firm bandaging for three months. This treatment should be adopted in all recent cases occurring for the first time. Operation (for all recurrent cases): If thorough immobilization has been neglected at first, it is useless later. Incision in a transverse direction over the edge of the affected cartilage. Open the joint. Remove completely all injured or displaced parts of the cartilage. Cut any tags of hypertrophied synovial membrane. Close without drainage. Retentive apparatus (when operation is refused or undesirable in chronic cases): The mechanism embraces the joint and while allowing flexion does not permit of any rotation."—(Grove's *Synopsis of Surgery.*)

7. *Rodent ulcer* is a carcinoma beginning in sebaceous glands. It generally occurs in patients over forty, and is of very slow growth. It begins as a smooth, rounded knob in the skin about the nose, eyelids, orbital angles, or cheeks, slowly increasing in size. In time ulceration occurs. The ulcer has a smooth, depressed base covered with ill-formed granulations, and bounded by a slightly raised, indurated, rolled-over edge. There is little discharge if sepsis is prevented, and little or no pain. The lymphatic vessels and glands are not affected, and dissemination does not occur. The ulcer spreads and destroys surrounding structures; even bone is not spared, so that the brain may ultimately be exposed.

Treatment: Free excision, allowing a margin of half an inch all around. If the situation or extent will not permit this, *x*-rays should be used for ten minutes daily till healing occurs.—(From *Aids to Surgery.*)

8. *Parenchymatous goiter:* "Operative treatment is indicated when there are symptoms referable to pressure on the air passages, esophagus, or blood vessels, especially if there are signs of commencing cardiac disturbance; and in goiters which are steadily increasing in size. The evidence of a goiter becoming malignant is also a reason for removing it by operation. Kocher considers it advisable to operate if the patient becomes breathless on making pressure on the goiter from side to side."

Adenomatous goiter: "The only treatment is to enucleate the adenomata or cysts from the gland. The thyroid is exposed by a transverse curved incision, the tissue covering the nodule is incised, and the adenoma shelled out."

Malignant goiter: "It is only in the earliest stages that a malignant goiter can be successfully removed. In the later stages complete extirpation is not to be attempted, as it usually involves the removal of a portion of the trachea or esophagus, and the operation generally proves fatal. Operative interference is often called for, however, for the relief of respiratory embarrassment. Tracheotomy may prove a very difficult and dangerous procedure, owing to the trachea being buried under the goiter and displaced or narrowed by it, so that it is not easy to reach the trachea or to introduce an efficient tube beyond the point of obstruction. A more certain method consists in exposing the goiter by an incision as for thyroidectomy, rapidly removing sufficient of the growth to expose the trachea and admit of a tube being introduced. If there is a retrosternal prolongation compressing the trachea within the thorax, a long flexible lead tube may have to be passed down beyond the site of the compression before the dyspnea can be relieved."

Exophthalmic goiter: "Excision of one lobe of the thyroid together with the isthmus and the pyramidal lobe is indicated in all cases that do not present degeneration of the heart muscle, with irregular pulse and low blood pressure. The superior thyroid artery of the opposite side may be ligated with advantage."—(Thomson and Miles' *Manual of Surgery.*)

9. The most frequent dislocation of the shoulder is the subcoracoid. "In *subcoracoid dislocation*, the head of the bone lies below the coracoid process upon the neck of the scapula. The tendon of the subscapularis is torn or stretched over the neck of the humerus. The supraspinatus, infraspinatus, and teres minor are either tightly stretched, producing external rotation, or torn (sometimes with great tuberosity), with internal rota-

tion. There will be found: Local contusion; restricted mobility; flattened out border of shoulder; head of the bone is felt below outer end of clavicle; elbow is displaced from the side outward and backward, and cannot be made to touch the chest wall when the hand is placed on the opposite shoulder; there is little or no shortening of the arm.

Treatment consists in reduction by manipulation or extension. For reduction by manipulation chloroform is advisable, and in most cases, as soon as the muscular spasm is relaxed, the slightest movements are sufficient to produce reduction.

Kocher's Method.—The forearm is flexed and the elbow pressed to the side; the arm is then fully rotated outward. The arm is now brought forward and upward to a right angle with the body, and then rotated inward, while the elbow is brought down over the body so that the fingers sweep the opposite shoulder. These movements relax in turn the tense parts of the capsule, and bring the head of the bone down to the rent, and then through it back into the joint.

Extension.—The patient is placed flat on a mattress on the floor, while the surgeon firmly grasps the arm and places his unbooted foot in the axilla. Traction is then applied till the contraction of the muscles is overcome and the bone slips back into its socket. Outward or upward traction may also be used.

After-treatment: "An adhesive plaster strap three inches wide is placed around the middle of the arm (so arranged as to permit two fingers to be introduced between it and the skin) and then drawn across the back and fastened just beyond the middle of the chest, a small folded pad of gauze being loosely placed in the axilla. A broad sling reaching from below the wrist to above the elbow completes the dressing. A sling is also used. . . . No initial dressing should remain on the part beyond two weeks; and from the beginning light daily massage over the joint (the adhesive dressing being in place) will promote absorption of the effusion, prevent adhesions, and restore muscle tone. Some passive motion after a week is allowable, with active motion beginning ten days later. After three weeks the adhesive or other dressing can be abandoned, and in a month the sling also."—(Moorhead's *Traumatic Surgery.*)

10. "*Varicose ulcer* is associated with varicose veins, and is common in the legs, especially when the small venules in the skin are involved. There is at first congestion, then exudation, and often eczema, and deeply penetrating ulceration. This leads to spread of the inflammatory process in the adjacent veins (phlebitis), and so it progresses. Inflammatory thickening increases the congestion, and cuts off arterial supply, thus adding to the weakening conditions, which are also intensified by any injury to the skin. The ulcer is liable to destroy the wall of a varicose vein and lead to alarming hemorrhage. The skin is dusky, congested, and often discolored by brown stains, which are due to destruction of red blood cells and freeing of their pigment. These ulcers, if neglected, are the most common origin of callous ulcers.

"*Tuberculous ulcer*, usually of the edematous type. It occurs in tuberculosis affecting any surface, and shows a tendency to heal, but to break down again, sometimes healing on one side and spreading on the other. The edges are healthy, or in spreading conditions the skin is often greatly thinned, dusky in color, and deeply undermined. The floor is pale, the granulations are edematous, and there are sometimes sloughs in the middle from poor blood supply. Where there is much discharge, as at the mouth of a sinus, the granulations are very large and flabby.

"*Syphilitic ulcers* occur in secondary syphilis from involvement of the skin in the disease, and more commonly in tertiary, from breaking down of a gumma. When the ulcer is superficial, the edges are 'punched out'; the base is covered with sloughs or scabs, and the surrounding skin is red. In shape it is circular, and, being multiple, the tendency is to coalesce and form irregular patterns (*serpiginous* ulcer), and it tends to heal at one side and spread on the other. When due to breaking down of a gumma the ulcer is deep and of any shape. The base is covered with grayish, broken-down gummatous tissue. The edges are clean-cut or undermined. The surrounding skin is often brown in patches."—(Buchanan's *Surgery.*)

THE SUPERIOR LONGITUDINAL SINUS IN INFANTS; ITS VALUE IN TRANSFUSION, AND FOR RAPID MEDICATION.

ITS ADAPTABILITY IN PROCURING BLOOD FOR DIAGNOSIS.*

BY LOUIS FISCHER, M.D.,

NEW YORK.

WHEN Marfan in 1898 suggested the use of the superior longitudinal sinus for saline injections he opened up a new field for both diagnosis and therapeutics. By this route we are not limited to saline injections, but can give other intravenous medication. Tobler advocates the use of the sinus route for blood transfusion, and it is to his credit that one of the greatest life saving measures is now being used in infancy.

During the last three years we find in the literature records of many successful cases of transfusion, and there is hardly an article but gives some new point perfecting the technique and enlarging upon the many adaptations of this particular anatomical point. In the many articles published we find Helmholz of Chicago, Dunn, Howell, and Vincent of Boston, Earl Tarr of Montreal, Lambert, Goodman, Peterson, and Fischer of New York, all advocating the use of the sinus route for transfusion.

When we consider the difficulty encountered in trying to enter a vein the size of the median basilic or even the femoral in infancy, and compare the ease with which we enter the sinus located at the posterior aspect of the anterior fontanel, our choice will readily fall in favor of the sinus route. The method is so simple that even an inexperienced operator need not hesitate to try it.

By the use of the longitudinal sinus we have a direct channel through which a small or large quantity of blood can rapidly be taken from, or added to, the circulation. Since time counts for a great deal in depleted and marasmic infants, the simpler the route, the more advantageous to the infant.

Many obscure conditions exist in which intestinal intoxication and faulty metabolism of the food elements is diagnosed. Before a positive diagnosis can be made, if a leutic basis is suspected a Wassermann or Noguchi reaction may be required.

The shock incident to the exposure of a vein and the loss of time encountered thereby are factors which one must bear in mind when an easier, safer, and more rapid method offers itself. The risk of infection, if one exposed the jugular, femoral, or median basilic vein must not be overlooked, especially in the weakened and puny infant. In one of my cases it took thirty minutes to expose and enter a vein at the elbow. The median basilic vein is at times so small that it looked, in the case of an infant one month old, like a very fine white cord.

This sinus is also adapted for the abstraction of blood, as in venesection during convulsions. The relief afforded by this means is rapid and the operation does not produce shock. Intracranial pressure can be relieved quickly and this method of local depletion serves as well as a lumbar puncture. This route is also adapted for procuring sufficient blood in the most rapid manner for blood culture. This point should be noted in suspected sinus thrombosis or malignant endocarditis. It is the most convenient place to give salvarsan injections. In septic diphtheria, where rapidity of action is necessary to bring the antitoxin into the circulation, the sinus route is indicated.

In hemophilia we have an hereditary or congenital disease in which bleeding may be interstitial or synovial, external, spontaneous or traumatic. The coagulation time is usually delayed. Peterson reports six transfused cases of hemophilia, one of these through the sinus route, with excellent results.

As a hemostatic, human blood acts in many instances rapidly—almost specifically. In a hemophiliac infant, following circumcision, two ounces of blood injected into the longitudinal sinus checked the hemorrhage within twenty minutes, although the infant had bled for four hours prior to this treatment. In another case of continued hemorrhage following an excision of cervical glands, postoperative treatment was unavailing until one ounce of human blood was injected by the sinus route.

Normal saline solution and sterile serums may be injected during or following atrophic conditions due to enterocolitis. By this means the column of blood can be replaced and a marked stimulus added to cardiac weakness. Such injections may be repeated once in twenty-four hours without producing shock. The first injection of 100 c.c. may be followed by one of 150 c.c., and later 250 c.c. may be injected every twenty-four hours until good stimulation is produced.

The sinus route is well adapted for the injection of sodium bicarbonate solution in cases of acidosis. Dextrose solution may also be injected by this method.

My own experience has been in both hospital and private practice. Especially good results were found in cases of marasmus, in bronchopneumonia with otitis media following influenza in which continued

*Presented to the Section on Diseases of Children, American Medical Association, June, 1918.

fever saps the vitality of the infant, in toxic scarlet fever, in postoperative glands, and in severe hemorrhage following circumcision in a hemophiliac case. I have had failures—especially moribund cases failed to respond.

In young infants of one or two months, no more than 30 to 50 c.c. of citrated blood was injected into the sinus at the first treatment. The pulse, temperature, and general condition were carefully noted, especially the surface temperature of the extremities. If no improvement was noted a second injection was given on the following day, using the same dosage of 30 to 50 c.c.

In another part of this paper I mention a marked antipyretic effect in febrile cases. In some cases a persistent high temperature was reduced soon after the transfusion. There seemd to be a decided antipyretic effect much greater than when antipyretic measures such as packs and eliminatives were used.

The nutritional value of the transfusion cannot be stated in pounds and ounces, but it will be apparent to every observer that the stimulation of nutrition is aided by transfusion. The weight curve usually stationary for weeks will rise soon after transfusion. The infant will show a steady gain after the second transfusion although the nutritional value of the food was not changed. I attribute the gain in weight not only to the added volume of blood to the circulation but to the stimulation resulting in better food metabolism.

Cherry and Langrock have asserted that in newborn infants the mother's blood can always be used with perfect safety for a transfusion.

It is interesting to compare the experience of pediatrists in various parts of the country. While many are enthusiastic and advocate the sinus route in preference to any other method, others are not so favorably impressed with this route. Unger in reporting a number of transfused cases says: "The superior longitudinal sinus was not selected because of the possible danger associated with its use, and because the median basilic vein affords a comparatively simple approach. If the inferior wall of the superior longitudinal sinus is accidentally perforated, there is real danger of injecting blood on the brain or of active hemorrhage occurring, especially in malænic patients where there is a hemorrhagic tendency. Using this route for aspirating blood for examination (syphilis, bacteriemia) is quite another matter, particularly in nonhemorrhagic cases." Unger's experience, therefore, is entirely different and not supported by the experience of Dunn and Howell of Boston, of Tarr of Montreal, and very many others. Regarding traumatism by repeated puncture of the vein, let me quote Tarr, who says: "It has been suggested that one is apt to produce considerable trauma by repeated puncture of the vein. I shall dismiss this supposition by stating that in one case in which I entered the sinus twenty-one times during the course of ten days no evidence of trauma was noted at autopsy. In twelve other cases that came to autopsy the vein was examined very carefully and not the slightest evidence of a puncture was noted. These cases had been punctured from one to ten times and all were examined within three hours after reaching the autopsy room."

There are a few points which should be noted in procuring blood by this method. Carefully done, there is no danger of infection or of perforating the inferior wall of the sinus, nor is there any shock following the operation.

Technique.—The infant should be wrapped in a mummy bandage, well pinned so that the arms and legs are confined, and placed flat on its back on a table. The head should be steadied on both sides by an assistant while the needle is inserted into the sinus. As a rule the sinus can be entered through the anterior fontanel up to the end of the second year. Anatomically the sinus does not vary. It grows wider towards the back of the head, hence, we should always utilize a point as far posteriorly as possible. As the needle is pushed through the posterior angle of the fontanel it should be directed downward and backward in line with the sagittal suture. The landmarks are positive, and with but little practice we cannot fail to enter the sinus. As the sinus lies very superficial we need not go deeper than 1 or 2 mm. For this purpose a needle one-half inch long of a 20 or 22-gage, with a sharp point, is best adapted. For withdrawing blood a Luer or Record syringe should be attached. As the needle penetrates the sinus, resistance is lessened and we encounter the same sensation which we feel when the needle enters the dura in doing a lumbar puncture.

We are now ready to aspirate sufficient blood for diagnostic purposes, or to transfuse the required quantity of blood or medication. As there is negative pressure within the sinus, before injecting it is better to withdraw blood, thus making sure we are actually in the sinus. The fluid, be it saline or salvarsan solution, is best given by gravity (Helmholz) and should be given slowly. A cylinder with a capacity of 30 to 100 c.c. may be used. One end of a piece of rubber tubing is attached to the cylinder and the other end has a connecting tip which fits into the needle. It is of advantage to have a stopcock either at the end of the cylinder or near the end of the tubing. The needle is inserted into a small syringe attached. By slight aspiration one can determine whether the sinus has been entered; if so, the syringe is detached, and the apparatus, which has been filled and the air expelled, is connected.

During the injection the infant should be closely watched, his color, pulse, and respiration noted. Vincent warns against injecting too rapidly, as increase of intracranial pressure caused vomiting and disturbed respiration, which corrected itself as soon as the flow of blood was checked temporarily. Air pressure in the tube should be released by detaching the syringe before the needle is withdrawn. There is no danger of losing too much blood by the puncture even though a large needle is used.

Case I.—A marasmic infant, breast fed, when one month old weighed 6 pounds. The infant did not nurse well, was cyanotic, and the extremities were cold. The stools were green and contained curds. The weight was stationary for several weeks, and the infant was restless. I decided to transfuse. Thirty cubic centimeters of citrated blood was injected through the longitudinal sinus and an immediate change in color of the skin, also in the surface temperature of the extremities was noted. The infant cried louder, seemed more satisfied, and the stools showed a better metabolism. In three days after the transfusion the infant showed a gain of two ounces in weight. As the first injection

was successful, it was decided to wait one week and then inject two ounces of citrated blood. After the second injection the infant gained in weight, nursed better, slept better, and seemed to have a new lease of life. So rapid was the improvement that what appeared to be a lifeless infant was transformed into a very lively specimen within three weeks after the second transfusion.

Case II.—An interesting case is that of a child eleven months old, in the ninth week of pertussis. The paroxysmal stage was unusually severe. Convulsions both tonic and clonic in character followed most paroxysms. The fontanel was tense and bulging, and there was extreme cyanosis, and several times a condition of apnea followed. With the aid of violent massage at the apex, the heart responded. After respiration and the circulation was re-established a needle was introduced into the sinus and 30 cubic centimeters of blood withdrawn. A rapid change took place, the paroxysms of cough, although as violent as before, were not followed by convulsions after the intracranial pressure was removed.

Case III.—A third case equally instructive was that of an infant seven months old, suffering from bronchopneumonia which lasted over seven weeks. The temperature ranged between 102° in the morning and 104° to 105° every evening. The pneumonia was of the wandering type spreading from lobe to lobe. The appetite waned. The stools contained undigested particles. During the third week pus and casts were found in the urine. The infant also developed a double otitis which showed *Staphylococcus aureus*. As the vitality was low I decided to inject an autogenous vaccine beginning with 50 million, gradually increasing every three days until 100 million per dose was injected. The vitality remained low, the appetite poor, the extremities were cold, there was restlessness by day and insomnia at night. It was evident that the infant was losing ground and that the prognosis was grave.

Through the longitudinal sinus I injected 75 c.c. of citrated blood, after which a marked change occurred. The temperature suddenly dropped to normal. The infant became brighter and stronger, and the pulse was of better quality. The nurse reported considerable improvement. The temperature remained normal twelve hours, then gradually rose, although not as high as formerly. Four days later a second injection of a similar quantity was given, also with a marked antipyretic effect. This infant lived for fourteen days, then succumbed to exhaustion and sepsis. I was, however, greatly encouraged by the immediate effect of this transfusion, but believe it was given too late in the disease to prove beneficial.

The donor in most cases was a relative of the child, and when an immediate relative was secured, agglutination and hemolysis reactions were not made. When, however, a strange donor was taken, all blood tests were made.

Many cases are reported in which an intravenous injection of 35 c.c. of blood in the new-born infant saved life. Lambert reports the case of an infant suffering with a hemorrhage of the umbilicus after the cord dropped off. With an intravenous injection of 35 c.c. of blood the hemorrhage ceased and the infant recovered from shock due to loss of blood.

Peterson of New York saw an infant 18 days old, in a critical condition, after bleeding six days. On the twelfth day there was a hemorrhage from the umbilicus which continued for six days. By the syringe-cannula method blood was taken from the vein of the donor, and 35 c.c. was injected into the longitudinal sinus through the anterior fontanel. Also an intramuscular injection of 15 c.c. was given. The hemorrhage stopped immediately.

Summary.—A study of the anatomy of the longitudinal sinus shows that it is one of the largest venus channels in the body. It lies at the posterior angle of the anterior fontanel, and by piercing the skin and dura we cannot fail to enter the sinus. The head of the infant is steadied by an assistant. Unless a special indication exists, neither local nor general anesthesia need be given.

The duration of the operation depends upon the skill of the operator. The technique is simple. When the needle is pushed through the dura into the sinus, the same sensation is felt as one notes in doing a lumbar puncture.

A short bevel point needle is preferred by some, while I have had best results with a long bevel point. This is an individual preference. Aseptic principles should be applied and the skin thoroughly cleansed with soap and water, then tincture of iodine applied.

The large caliber of the sinus is especially adapted for procuring blood rapidly, when a Wassermann reaction is desired, or when intravenous medication or normal saline solutions are indicated.

Salvarsan injections are conveniently given through the longitudinal sinus.

The shock, associated with incision and exposure of a vein, be it ever so slight, is avoided when using the sinus route; therefore, when phlebotomy is indicated, as in convulsions, or when intracranial pressure exists, or in toxic and in septic diphtheria in which intravenous injections of antitoxin are required, they should be given through the sinus route.

Enthusiastic reports following sinus injections are based chiefly on the simplicity of the method and the rapid reaction noted. The stimulation of nutrition following sinus transfusion in marasmus far exceeded my expectations.

I am indebted to Dr. Minsk, former Assistant Resident of the Willard Parker Hospital, for his kind assistance.

Kala-Azar in Tunis.—Nicolle states that 50 cases of this affection have been seen in the past 10 years in which the diagnosis was confirmed by the microscope. From three-fourths to four-fifths were seen in the children of Italian migrants. The chief Italians to suffer are those of Sicily and Malta, in both of which islands the young children associate much with dogs. The native Tunisian is seldom attacked.—*Bulletin de la Société de Pathologie Exotique.*

PATENT FORAMEN OVALE AND ITS RELATION TO CERTAIN CARDIAC MURMURS.*

By W. F. R. PHILLIPS, M.D.,

CHARLESTON, S. C.

PROFESSOR OF ANATOMY, MEDICAL COLLEGE OF THE STATE OF SOUTH CAROLINA.

DURING the academic sessions of 1916-17 and 1917-18 there were dissected in the regular courses of anatomy of the medical school with which I am connected twenty-three adult cadavers. The hearts of all were examined with reference to the existence of any direct communication between the right and the left atria, either as caused by the persistence of the foramen ovale or by defective development of the interatrial septum.

In eighteen of the twenty-three hearts a direct communication was found, and in five of the twenty-three there was no such communication. With but one exception the right orifices of the communications were in the fossa ovalis; in the exceptional case the right orifice was in the limbus foraminis ovalis. The left orifices of all were within the area of the left atrium that corresponded to the area of the limbus and fossa ovalis of the right atrium. The location of the right orifices was variable, but generally in the upper half of the fossa, and often so covered by the projecting border of the limbus that the orifice escaped notice on superficial examination. On the left side the orifices of the communications were placed either more cephalically or more ventrally than on the right side, so that the passageways ran obliquely through the membranous floor of the fossa or between it and the limbus. In length the passageways varied from oblique slits to channels of some length, several being about three-quarters of an inch from orifice to orifice. Some of the long channels showed cul-de-sacs extending from them. The caliber of the communicating openings varied from pin-hole to pencil-size or larger in diameter, one was large enough to admit the passage of the tip of the little finger. The shape of the openings on the right side was equally as variable as the locations; some were mere slits with slightly rounded margins, others dimple-like to funnel-like depressions, and others of irregular shapes. On the left side the openings were more regular and tended to resemble more or less the orifices of the foramina of the small cardiac veins. In several instances two openings occurred and in one case a forked channel, having one orifice on the right side and two on the left, was observed. The variability in location, shape, and size of the openings appeared insusceptible of classification into types. From the oblique course of the openings all were valvular in action, permitting fluid to flow through them only in one direction, and this was from the right atrium to the left atrium, with the exception of the opening located in the limbus; this opening permitted fluid to pass only from the left to the right atrium. The ages of the cadavers, as judged from appearances, were from young adult to advanced life. The clinical histories of all were unknown. All the openings observed were unquestionably failures of the foramen ovale, either to develop normally or to close normally after birth and, therefore, are to be regarded as cases of patulency of the foramen ovale in adult life.

The fact that such patulency was frequent has been remarked by anatomists and by pathologists from time to time and with more or less emphasis; it has been commented on also by clinicians, but with less frequency and decidedly less emphasis than the prevalence of the condition deserves, at least such is the impression given me by an examination of some of the current text and reference works. The series of hearts here reported shows a ratio of persistency as against complete closure of the foramen ovale of 18 to 5, or 78 per cent. persistency to 22 per cent. closure. This is a ratio greater than any other so far within my knowledge. There appears to be wide variability in the observed frequency of unclosed foramen ovale in adult life. Quoting but a few among the relatively recent writers referring to the subject: Cunningham[1] gives the ratio of patency to closure as about 1 to 5, that is about 20 per cent.; Parsons and Keith[2] as over 26 per cent., as determined from a collective investigation of 399 hearts; according to Welch and Rolletson,[3] Firket reported the foramen unclosed in 34 per cent. of his cases; Sewall[4] quotes Hochsinger as authority for stating that Kolb and Wallman found the foramen persisting in no less than 44 per cent.; and Babcock[5] states that according to Romberg the foramen persists in at least half of all cases. It may be interesting and not inappropriate to notice some of the non-statistical observations of a few of the earlier writers mentioning the persistence of the foramen ovale in adult life: Andrew Blake,[6] in reporting a case in 1828 of foramen ovale found open in a soldier dying of tuberculosis, quotes "that able anatomist, the late Mr. Shaw," as having observed that the condition "is so common that we cannot attach much importance to it." Farre,[7] in 1814, writes: "In considering the structure of the fœtal heart, the probability would seem great, that the valve of the foramen ovale might frequently be imperfectly united to the annulus foraminis ovalis by the pressure to which it is subjected in the double circulation after birth. But yielding up probability to antomical demonstration, an aperture of communication through the septum auriculorum is actually so often met with in subjects brought into dissecting rooms attached to the anatomical schools, that the observation of the student who has not witnessed it, even in adult life, must have been exceedingly limited." Allan Burns,[8] in 1809, remarks that "We very seldom find the foramen ovale and the ductus arteriosus both open, but we very frequently observe the foramen ovale pervious even in very advanced age." In the second edition of his "Traité de la Structure du Cœur," published in 1783, Senac[9] states: "Ce trou, bien loin d'être bouché dans l'adulte, est ouvert dans la plûpart des sujets, même de ceux qui sont parvenus à une extrême vieillesse." While Le Cat[10] is quoted in 1741 as follows: "This last winter I had opened a great number of dead bodies of men grown, and did not

*Read at the meeting of the American Climatological and Clinical Association, Boston, Mass., June 5, 1918.

find the foramen ovale open in any of them. The oldest male subject in which I found it open was a lad of fifteen years of age. Of twenty bodies of women, which I examined, in seven I found the foramen ovale open. Among the number of openings that remain of this foramen, there is a great variety in their shape, and in the number of cicatrices or adhesions of the valve." Le Cat then describes and figures three general types to which the openings may be reduced. Cheselden,[11] in 1722, in describing the method of closure of the foramen ovale by the adhesion of the valve, observes: "Sometimes this valve does not quite cover the foramen, in which case a small quantity of blood may possibly flow from the left auricle to the right, and so circulate twice through the lungs to once through the body, but none could flow from the right to the left and escape the lungs, which might be a bad consequence. Some have imagined, that men who have this passage open, cannot be drown'd: but tho' this passage has sometimes been found open, no man has been yet seen, that we have heard of, that could not be drown'd. I have seen the foramen open in a man that was hanged, to whom one might justly expect it should have been as useful as in the case of submersion."

All the subjects examined by me were negroes, showing less racial admixture than that of quadroon; it may be, therefore, that this increased ratio is a racial characteristic, but this is not to be considered as other than a very contingent explanation. I am inclined to think that present-day anatomical methods of preserving material, and the more leisurely and critical examination that such methods permit, will enable the finding of openings that in the ordinary post mortem procedure of examining fresh and unfixed hearts may easily be overlooked, and that the larger ratio I have found is due to dissecting room methods of examination.

The series of hearts herein reported is small numerically, and I should hesitate to depend on it as an index of the frequency of unclosed foramen ovale in the adult were it not more or less supported by the observations of others, and also by my own impressions drawn from an extended anterior, but unrecorded, experience in dissecting room work. The fact that such openings are frequent, almost the rule rather than the exception I am tempted to say, would appear to attach to them a clinical interest that they have not heretofore had as probable, and doubtless frequent, factors in the causation of cardiac murmurs, and particularly of that class of systolic murmurs unassociated with any other evidence of cardiac impairment. The frequency of the occurrence of these openings through the fossa ovalis in adults of all ages and their almost invariable valvular nature, indicates that they are not inconsistent with perfect cardiac function, and that so far as constituting a pathological condition they are virtually, as Humphry designates them, "without clinical significance." However, as factors that may and do cause unquestionably now and then signs that may be mistaken for those of pathological changes in the heart they are worthy of consideration.

The variability observed in the position, caliber, shape, and length of these openings, to which reference has already been made, would indicate, *a priori*, great variability in the physical evidences, as murmurs, that may be due to the existence of these openings. It is not surprising, therefore, that the clinical signs of these openings are not better understood at present. Romberg, according to Babcock,[5] states that the bruit caused by an unclosed foramen ovale is usually a loud systolic murmur, heard throughout the cardiac area, particularly over the base and apparently not limited to any area. Humphry groups the auscultatory sounds of all septal defects together and writes that "on auscultation there is commonly heard to be a loud, long, systolic murmur which can be traced with varying intensity over the whole of the precordial region, over the back of the chest, and is conducted widely in all directions." According to Hirschfelder,[12] "occasionally there is heard a well-defined presystolic murmur which is maximal" over the left third intercostal space, "and which when present is the most characteristic sign of the open foramen ovale." Thomas Oliver[14] describes the murmur as soft systolic, over the mitral area, loud, blowing, and somewhat rasping, over the base of the heart and mid-sternal area, faint as the aortic area is approached, loud and prolonged as the pulmonary area is approached, along which the murmur is conveyed for about half an inch. Sewall[4] reports the case of an infant, apparently less than a week old, clinically diagnosed as patent foramen ovale and the diagnosis confirmed subsequently by autopsy. In Sewall's case the "murmur was heard with the first sound of the heart, and was short, faint but distinct. The murmur was heard most distinctly in the segment which included the base line of the heart and curved over the right border of the sternum. In other words, the murmur had its greatest intensity in the area of the chest wall most closely approximating the auricles. Again the murmur appeared to be presystolic both in time and character. That is to say, in contradistinction to systolic murmurs. Its ending was abrupt, not gradual, its accent was acute, not grave."

The want of conformity to definiteness of type, or types, of these openings in the fossa ovalis, while it renders the certain recognition of their presence very difficult, sometimes doubtless impossible, and in so doing divests them of the clinical significance attaching to definitely recognizable conditions, yet it invests the significance of cardiac murmurs and their accurate determination and discrimination with a greater degree of importance and responsibility. In the light of the probability of openings of the kind herein described, cardiac murmurs, especially systolic ones, unaccompanied by other corroborative evidence of functional impairment become less indicative of real cardiac incapacity. How many healthy hearts have been doomed because of murmurs caused by open foramen ovales no one can say; one may guess. Apart, however, from any relation to cardiac murmurs, the frequency of openings in the fossa ovalis has a clinical importance not lightly to be passed by, and that is that these openings are potential avenues for the passage of emboli

from the venous circulation directly into the arterial circulation, the so-called "paradoxical embolism" of Zahn. That emboli do so pass has been demonstrated. Therefore, a foramen that does not invariably and completely close is always a menace, according to its degree of patulency and the occurrence of conditions favoring thrombosis and embolism in the venous side of the vascular system. It is also interesting, if not worth while, to quote Allan Burns' observation regarding the association of open foramen ovale with cardiac asthma: "This," says Burns, "is a much overlooked cause of dispnoea, but still it is one you will very frequently be called on to remove; I have seen many examples of this kind of asthma, and have ascertained, by dissection, the real cause of the symptoms."

THE SIGNIFICANCE OF EARLY HEART LESIONS.*

BY JOHN L. HEFFRON, M.D.,

SYRACUSE, N. Y.

DEAN AND PROFESSOR OF CLINICAL MEDICINE OF THE COLLEGE OF MEDICINE OF SYRACUSE UNIVERSITY.

In no department of internal medicine has there been during the last two decades a greater advance in knowledge than in that of diseases of the heart. Important discoveries in the anatomy and in the physiology of the normal heart have contributed greatly. Research work in bacteriology has demonstrated that very many disease-producing bactera besides those formerly recognized as causative agents are capable of invading the heart in the course of an infectious disease, and it is generally agreed that the cause of rheumatic involvement is bacterial, though it can not be said to-day that there is unanimity amongst bacteriologists as to its identity. Pathologists have demonstrated that the cardiac lesions due to infections not only are not confined to the valvular structures of the heart, but that the invasion of the musculature of the heart is of much more significance.

By the use of the newer graphic, illuminating, and acoustic instruments of precision more exact observations have been recorded and by their help the entire subject of the cardiac arrhythmias has been clarified and rewritten in a form that seems permanent. All of these advances have made possible a surer prognosis. The heart to-day is considered to be an organ which can withstand serious pathological injuries and yet regain and maintain a considerable degree of power.

Many of us in this society were educated when the teaching concerning the relative importance of valvulitis was exactly the opposite of what it is to-day. We were taught the pathological changes in valves and the doctrines of the backset of the blood and were carefully drilled in the detection of murmurs and their exact location, and in the tracing back of the damaged valve the effect upon the general circulation and on the integrity of various organs. Very little was taught about the muscle of the heart. The modern conception of the physics and pathology of the heart is quite different. The clinician estimates at the beside the contractibility, the excitability, the conductivity, the rhythmicity, and the tonicity of each heart he studies.

The driving force of the heart due to its muscular contractions is the most important. If the driving power of the ventricles be efficient the circulation is maintained. In a disabled condition of the heart muscle, it is the failure of the forward propulsion of the blood, not back pressure, which retards the circulation and thus disturbs the function of organs, permits the collection of blood at the doors of the auricles and makes edema possible. Heart disease as a whole may be considered as a disturbance of the driving force of the heart muscle.

The force of every heart is a personal one and must be measured by the maximum amount of work which an individual can do habitually with perfect comfort.

A heart capable of exerting its maximum force with perfect comfort is of normal size, and of normal rhythm, and of normal rate. Any departure from this standard must of necessity change the classification of the heart presenting it.

The size of the normal heart is practically constant. It is accurately ascertained by an x-ray examination. It can be determined with relative accuracy by correctly locating with the stethoscope the apex beat and the second sound at the aortic cartilage. Palpation and percussion are valuable but less precise. The heart undergoes both hypertrophy and dilatation from causes outside of it. When such conditions are eliminated and the heart is still found enlarged or dilated, it is of itself an indication of a fault which must be explained.

The rhythm of the normal heart is exact, except in childhood and in adolescence. Sinus arrhythmia is but evidence of an instability of nerve control normal to those periods of development. Paroxysmal tachycardia, observed often in toxic states or even due to pressure from a stomach distended with gas or overloaded with food, particularly in

*Read at the Annual Meeting of the American Climatological and Clinical Society, Boston, June 5, 1918.

the neurotic, is common. We have been in the habit of ignoring this symptom and it is of relatively little consequence. In chronic toxemia, as in Bright's disease, it adds to the embarrassments already existing. Premature contractions never fail to make themselves known to the consciousness of the patient. They are startling at first because of the heavy thud of the delayed beat. Premature contractions have been observed in those who otherwise have seemed perfectly normal. Auricular fibrillation and auricular flutter are of more significance. The advent of either one of these irregularities is positive proof of a considerable enfeeblement of the heart muscle. In some cases activities can be maintained and a comfortable life enjoyed for many years, but the average lease of life after the establishment of one of these irregularities which, as a rule, is permanent, is not more than ten years. Either may accompany another cardiac lesion, particularly mitral stenosis, but either can develop independently of other involvement. Cases in which paroxysms of tachycardia have later been accompanied by premature contractions and ultimately developed suddenly auricular fibrillation are already recorded and have undoubted significance. From those presenting such a series of phenomena one rarely fails to get the history of some infectious disease occurring in the early years.

J. P. at 12 was an unusually well developed boy. He had had many severe infectious diseases, including diphtheria, pneumonia, and typhoid fever, but without known cardiac involvement. After severe exertion he developed symptoms of heart failure, and dilatation and mitral murmur were discovered. A short period of complete rest restored the heart to an apparently perfect condition. In early manhood he had many brief attacks of paroxymal tachycardia attributed to errors in diet. At about 30 an occasional premature contraction was noticed but he was not inconvenienced. In the forties these attacks increased in frequency and were thought to be longer when too much tobacco was smoked. At 45, while exercising, he suddenly developed auricular fibrillation with a very rapid pulse. Under rest and digitalis the irregular pulse was brought down into the seventies and has been kept there. With care he is able to do a considerable part of his work as a counsellor at law. I have observed this case for some years and can detect no advance so far. There is no accompanying cardiac lesion or other complicating pathological condition.

Heart block is interesting and of importance in prognosis when progressive. A complete heart block, if the pulse be not reduced below the limit at which an uninterrupted circulation in the brain can be maintained, need not shorten life greatly.

In a woman under my observation for minor ailments throughout my entire practice, and now 76 years old, complete heart block with a pulse of 38 to 40 has been known to exist for at least five years. She is still active and doing her own housework for a family of four adults. On two occasions, when overexerting herself, she has lost consciousness for a period just long enough to fall and she has had more frequent dizzy spells. She had rheumatism early in life and phlebitis repeatedly in later years, but valvulitis can not be diagnosed from any murmur. Her heart is moderately hypertrophied. Her blood pressure is 170/80 and her hemoglobin is 80.

True pulsus alternans is always of grave significance. It usually expresses extensive degenerative changes and feebleness of the heart muscle. The majority of cases with this symptom do not survive two years.

The heart has a normal rate of contracting. A rapid pulse is one of the manifestations of a weakening muscle, but there are so many physiological and pathological conditions that are expressed by an increase in the pulse rate that it is always necessary to exclude extracardiac causes before considering the rate alone as a factor in prognosis.

That a heart of normal size, rhythm, and rate may present murmurs is a common observation. In many perfectly healthy young men a murmur may be heard at the situation of the pulmonary artery, due to a slight contact of that vessel with the chest wall. Cardiorespiratory murmurs, superficial, heard along the left costal arch, like a puff of air pushed out of an overlapping tongue of lung by each stroke of the heart, are relatively common. Functional murmurs due to temporary causes are not uncommon, but require careful differentiation. All of these are of no prognostic significance. But murmurs are heard at the apex, systolic, presystolic, or diastolic, and at the aortic cartilage, systolic or diastolic, which are significant of valve lesions, even though the heart be of exactly normal size and function.

The noisest murmur is not necessarily the one of most importance. One finds an aortic regurgitant murmur at times that is loud, but not accompanied by evidence of disturbance on the part of the heart. But even a prolongation of the second sound at the apex with a suggestion of a change in the tone, if accompanied by a fine thrill at the apex, is indicative of a beginning mitral stenosis and is of the utmost importance, however perfectly the heart muscle is doing its work. Mitral stenosis is a defect ultimately attended by grave consequences in every instance. Mitral regurgitation, however, is a condition to which the heart can accommodate itself perfectly for many years.

A young man of 24 came to me recently saying he had been refused for military service on account of his heart and because of underweight. He also said he fainted easily. He did not know that he had had heart disease, but he gave the history of infectious diseases, including tonsillitis, in childhood. He was perfectly proportioned, but was six pounds under the average weight for his moderate stature. He was very highly organized nervously. His heart was exactly normal in size, regular, of normal rhythm and rate, and his blood pressure was normal. At the apex there was a loud systolic murmur propagated to the left to the midaxillary line. After exercise the proportionate increase of rate was no more than normal. On questioning him, it was developed that his fainting spells had never occurred except when his imagination had exaggerated the effect of a gruesome recital—as Billy Sunday's sermon to men, an orator's description of the carnage of battle, etc. If he had been up to normal weight and I had been examining him for military duty, I should have been obliged to pass him. It was perfectly evident, however, that he had had nitral valvulitis with little or no impairment of the muscle of his heart.

At 15, C. F., had a savage attack of acute articular rheumatism with carditis, and that passive congestion of the lung often called pneumonia. He was confined to bed about three months. For a long time the persistent symptoms of cardiac impairment were in evidence. The heart finally became strong, the various evidences of impairment receded and disappeared to such an extent that ordinary methods of examination did not reveal a murmur except after most violent exercise, and even then there were no other evidences that the heart was not up to its job. He escaped further illness. He went through college and through a medical school with credit. He passed an exacting examination

for life insurance. When he was 25 and an interne in a hospital, he contracted an acute infection of first one and then of the other tonsil without suppuration. After a couple of weeks, during which his heart had remained as before, he got up, was about a few days, and then developed an acute, toxic, ascending, multiple neuritis. His heart was watched with great care. It gave no evidence of a reinfection, but with added weeks in bed, and possibly from the influence of the toxins producing the neuritis, his heart became dilated and rapid and the same old murmurs reappeared. The neuritis ran its course rather quickly for such an extensive involvement. At the end of four months from the initial infection the dilation had diminished so that the apex was inside the midclavicular line; the rate was in the seventies while at rest, and the murmur was faint. It is probable that he will regain good muscular tone, and that he will be able to engage in the activities of his chosen profession.

G. S., 43, a farmer, consulted me because, as he said, "my wife complains that my heart makes so much noise that she can not sleep." He had had no illness except influenza ten years ago. For the past year he had noticed a noise in his heart that is heard when standing and when lying and that is becoming somewhat louder. The heart was exactly normal in size, his pulse was 68, his blood pressure was 145/45, and his hemoglobin 85. Heard plainest at the aortic cartilage in diastole, there was a musical murmur like the twang of a high-pitched string of a violin. It really was transmitted so that it could be heard by anyone standing near him. The pulse was collapsible, as indicated by the low diastolic pressure. This man had done all the heavy work on a farm all his life and came not because he felt ill but because he was curious to know what the noise was and what it meant. There was no doubt but that he had aortic regurgitation with possibly a rent in one of the cusps.

A. P. came under my care for varicose veins when he was 63. He was born in England and began life as a blacksmith. He knew he had a heart lesion early in life and on that account had educated himself for business and became an iron manufacturer and at 60 had retired. With every beat of his powerful heart his whole body reacted. The arteries were greatly dilated, the ascending palatine being as large as "night crawlers," and writhed from their beds with each pulsation. His heart was hypertrophied with apex inside the mammary line. It presented a mitral systolic and an aortic diastolic murmur of great intensity. His pulse was always in the seventies when at rest, and never above 100 after exercise. Four years later Dr. Jacobson did a Whitehead operation for the removal of the pile bearing area under ether which he took without trouble. At the age of 76, after a siege with whooping cough contracted from a young member of the family, failure of heart supervened, rapidly progressed, and terminated a life that had been tolerable and not devoid of usefulness.

In my early practice I saw many men who worked in the salt yards. These men were always exposed to wet and bad weather and their work made necessary strong use of the muscles of the arms and trunk. In routine examinations the hearts of these men were almost always found to be hypertrophied, often more or less irregular, and sometimes gave various murmurs. It made one wonder, at that time, that their work could be continued; but, as the heart condition was a discovery which had little to do with the illness for which treatment was required nothing was made of it, but observations were continued sometimes over a considerable period. Many of these attained a good age and comparatively few of them died because of heart failure. In thirty-seven years of practice a considerable number of cases of acute heart disease have come under my care and some of them have been observed for many years. Of those who have survived the initial shock the majority have gone on with their chosen work successfully and with considerable comfort.

Very many of the adults who come to the consulting room with some form of cardiac impairment come without previous knowledge of an existing heart lesion, but I suspect that the great majority of the cardiac lesions that limit activities beyond the meridian of life trace their beginnings to childhood or to the adolescent period when infections are common. It is certain that very many cases of infectious disease in childhood involve the heart without recognition. In rheumatism and in scarlet fever the heart is usually watched with care, but in the other infections, all of which are potential causes of heart lesions, we had not been taught to be so careful. Another thing is certain, a destructive process, however slight, leaves a scar. No one who has studied preparations showing the results of experimental infections of the hearts of the lower animals can fail to have been impressed with this. In hardly any heart case, not even in the degenerative changes which are attributed to age, if there be any degenerative change in a heart due to age alone, does one fail to find the history of some infectious disease. It would be of the greatest interest to know the medical history of those grand old men who have maintained intellectual and physical power to a great age, like Gladstone, Premier of Great Britain at the age of 84; for one of the early manifestations of beginning heart failure is loss of memory and difficulty to sustain mental effort. This is a point of great importance now, when hundreds of thousands of our young men are being judged as to their fitness for military duty, and when hundreds have been under observation for a disorder roughly named "soldiers' heart." The standpoint of the deciding physician in these instances must be that of the State—not of the individual. His duty is to say whether the man examined is capable of military duty, not what remote effect will military duty have on the heart of the man. The conclusion that in this emergency of war the State can be sure of obtaining efficient service from a man presenting some of the forms of an impaired or disordered heart, is not the same as saying that military service is good for such a man or not harmful for his future interests. If his condition promises to permit him to meet the temporary exigency, he must be passed regardless of this as of other possible dangers he may meet. This attitude warrants the assertion of Lewis in his report on the work done at Mount Vernon Hospital on disorders of the heart, when he says: "The presence or absence of murmurs (wherever they may be audible) is of no value in estimating the soldier's capacity for work."

I cannot agree, however, that evidence of a damaged valve is of no importance in prognosis. It certainly means friction, and friction means wasted energy, which in the long run must tell upon the driving power of the heart.

It is probable that what we have hitherto called "heart strain" is fundamentally made possible by some unrecognized lesion of some structure in the heart, for all persons under identical conditions do not develop acute dilatation or other disorder of the heart under great physical strain, and, on the other hand, after epidemics of mild infectious

diseases, say of measles or even of catarrhal colds, we have observed in some active boys the symptoms of slight cardiac failure and have found dilatation and murmurs.

From the standpoint of the individual I still consider it to be our duty to acquaint our patients with the facts, emphasizing all that are favorable, but inculcating definite rules by which, without apprehension, they can know when they have overstepped the limits of their own cardiac strength, for it is the intelligent response to the information of failing strength which the heart always gives that makes a long and useful life possible to those with this handicap. In such cases, too, it seems to me a duty to attempt to direct the future career of such, and especially of children and adolescents, for there is little question that, though the heart muscle needs exercise for its development, an occupation demanding heavy and continuous work on the part of a heart that is even a little impaired must cause the earlier appearance of the evidences of beginning heart failure.

FIFTY CASES OF TUBERCULOSIS, MAINLY OSSEOUS AND GLANDULAR, TREATED WITH TUBERCULIN CONTRASTED WITH FIFTY CASES TREATED WITHOUT TUBERCULIN.*

By RICHARD COLE NEWTON, M.D.,

MONTCLAIR, N. J.

CONSULTING PHYSICIAN AND CHIEF OF TUBERCULIN CLINIC, MOUNTAINSIDE HOSPITAL, CHIEF OF STAFF, MONTCLAIR FRESH AIR AND CONVALESCENT HOME.

AND

SIDNEY A. TWINCH, M.D., F.A.C.S.,

NEWARK, N. J.

ATTENDING SURGEON, HOME FOR CRIPPLED CHILDREN.

Inasmuch as there seems to be at the present time a demand for facts relating to the clinical use of tuberculin in the treatment of all forms of human tuberculosis, it has seemed to us expedient and proper to give, briefly, the salient points regarding our experience in this work. Owing to the fact that the number of cases in which a course of treatment by tuberculin has been carried out is quite limited, we have been obliged to content ourselves with reporting only fifty such cases, most of which were treated in the Home for Crippled Children in Newark. As this institution has been in active operation for twenty-five years, there was no great difficulty in collecting fifty consecutive cases treated without tuberculin, and except in a very few instances, in determining the final outcome in each case. We have thought regarding the cases treated with tuberculin that it would be more satisfactory to report only cases which we have personally observed and treated than to augment our rather limited number of such cases by adding reports from the practice of others. So far as we are aware no other orthopedic hospital except the Home for Crippled Children in Newark has used tuberculin long enough to furnish any considerable number of histories of cases treated by this method.

Its use in this institution began in 1915 and since at least between two and three years must elapse before the treatment of any considerable number of cases with tuberculin can be concluded and the results ascertained, it followed, somewhat to our surprise, that we could barely collect fifty completed cases from our hospital and private practice. However, as time goes on, this difficulty is almost sure to decrease, and inasmuch as hospitals and sanatoria can furnish a great number of histories of cases of tuberculosis treated without tuberculin, the comparison of large numbers of finished cases by the two methods will become possible.

Fortunately, successful tuberculin treatment requires the greatest nicety in keeping the records of each individual case just as it does in the administration of the remedy, so that it is reasonable to expect in a few more years such an abundance of accurate clinical histories that indisputable conclusions can be drawn from them.

Pending this increase of statistical knowledge, the data we have collected will prove of interest and will help in the world-wide fight against tuberculosis. The following tables will show as conclusively as possible, the more important facts which our study has brought to light.

Table I summarizes the results in the treatment of fifty cases in the Home for Crippled Children without tuberculin and Table II shows the results of treatment in an equal number of cases treated with tuberculin in the Home for Crippled Children, in the Mountainside Hospital Clinic and in private practice.

We will give the conclusions which have been drawn from these tables and refer to some special cases by number.

Without tuberculin 16 recovered, or 32 per cent.; 25 died, or 50 per cent.; 9 are still wearing braces and under treatment, or 18 per cent.

With tuberculin 33 recovered, or 66 per cent.; 5 much improved, or 10 per cent.; 6 died, or 12 per cent.; 5 still under treatment, or 10 per cent.; 1 discontinued treatment, or 2 per cent.

Of the cases treated without tuberculin the total period under treatment for the entire number was 235 years and 9 days; the average length of the treatment for each patient was 4 7/10 years.

Of those treated with tuberculin the total time of treatment for all the patients was 54 years, 11 months and 9 days, an average for each patient of 1 year and 1 month.

Of the 16 cured without tuberculin the average period of treatment for each case was 5¼ years.

Of the 33 cures with tuberculin the average period of treatment for each case was 11½ months.

Of the 25 deaths without tuberculin the whole period of treatment was 72 years, 11 months, 9 days, or 3 years, 14 days for each patient.

Of the six deaths of those treated with tuberculin the total period of treatment was 4 years, 9 months, and 29 days, or an average of 9 months, 13 days for each patient.

Of those treated without tuberculin, nine are still under treatment.

*Read before the American Climatological and Clinical Association, June 5, 1918.

TABLE I.—FIFTY CONSECUTIVE CASES OF TUBERCULOSIS TREATED WITHOUT TUBERCULIN IN THE HOME FOR CRIPPLED CHILDREN IN NEWARK, N. J.

No.	Name.	Age.	Sex.	Nativity.	Occupation.	Diagnosis.	Date of Inception.	Period Under Treatment.	Result.
1	M. S.	7	Male	U. S.	Minor	Pott's disease	4 years of age	11 yrs.	Died 1916.
2	L. M.	14	Female	U. S.	Minor	Tub. coxitis, left	Jan. 26, 1905	3 yrs.	Is cured.
3	L. W.	6	Male	U. S.	Minor	Dorsal, Pott's	Feb. 1906	2 yrs. 1 mo.	Died 1908.
4	M. B.	5	Female	U. S.	Minor	Dorso-lumbar, Pott's	1902	6 yrs.	Died April, 1910.
5	P. G.	5	Female	U. S.	Minor	Sacroiliac, Pott's	Feb. 1906	2½ yrs. (except 1 mo.	Died Nov. 9, 1909.
6	L. S.	11	Female	U. S.	Minor	Tub. ankle dbl.	1904	2 yrs.	Cured.
7	T. C.	4	Male	U. S.	Minor	Tub. os calcis, right	March 1906	2 yrs.	Died March 12, 1907.
8	M. F.	6	Female	U. S.	Minor	Tub. coxitis, right	June, 1906	8 yrs.	Cured. (Right leg 1½ in. short.
9	M. H.	10	Female	U. S.	Minor	Tub. ankle	June 7, 1904	2½ yrs.	Cured.
10	H. P.	9	Male	U. S.	Minor	Tub. coxitis	October 1906	6 mos.	Died April 5, 1907.
11	K. O.	6½	Female	U. S.	Minor	Tub. coxitis dbl.	1900	Bet. 5 and 6 yrs.	Cured.
12	O. P.	4	Male	U. S.	Minor	Tub. coxitis, right	Feb. 26, 1907	2½ yrs.	Died May 23, 1909.
13	A. K.	5	Male	U. S.	Minor	Tub. coxitis	1904	8 yrs.	Cured.
14	R. F.	10	Female	U. S.	Minor	Tub. meningitis	April 14, 1907	9 days	Died April 23, 1907.
15	E. K.	5	Male	U. S.	Minor	Pott's disease	5 yrs. of age	11 yrs.	Still wearing jacket.
16	A. T.	7	Male	U. S.	Minor	Tub. tarsus, left	Feb. 1907. Recurrence 1916	2 yrs.	Discharging sinus.
17	T. K.	5½	Male	U. S.	Minor	Tub. coxitis, right	Dec. 16, 1905	1½ yrs.	Died 1907.
18	J. McC.	3½	Male	U. S.	Minor	Tub. knee, right	1907	11 yrs.	Still wearing cast.
19	M. R.	17	Female	U. S.	Minor	Tub. hip	When small child	1 yr.	Died 1907, age 17 years.
20	M. C.	3½	Female	U. S.	Minor	Tub. coxitis	April 1907	11 yrs.	Still has discharging sinuses.
21	J. S.	16 mo.	Male	U. S.	Minor	Tub. coxitis	June 1908	1 mo.	Died July 13, 1908.
22	R. G.	7	Female	U. S.	Minor	Tub. coxitis	June 11, 1908	4 yrs.	Cured.
23	S. M.	7	Male	U. S.	Minor	Pott's disease	June 1904	10 yrs.	Still under treatment in N. Y
24	H. H.	6	Male	U. S.	Minor	Tub. coxitis, left	July 1908	5 yrs., in bad shape.	Still has discharging sinuses.
25	F. S.	17	Male	U. S.	Minor	Tub. coxitis, right	At the age of 16 years	1 yr.	Died 1908, 17 yrs. of age.
26	A. W.	6	Male	U. S.	Minor	Cervical, Pott's	Dec. 31, 1908	2 yrs.	Cured.
27	A. E.	6	Female	U. S.	Minor	Tub. coxitis	Feb. 1909	3 yrs.	Cured.
28	L. P.	10	Female	U. S.	Minor	Cervical tub.	Feb. 1909	3 mos.	Died May, 1909.
29	J. R.	2	Female	U. S.	Minor	Tub. knee, left	1902	10 yrs.	Cured.
30	B. G.	9	Female	U. S.	Minor	Pott's disease	March 1908	3 yrs.	Died March, 1911.
31	W. B.	12½	Male	U. S.	Minor	Tub. hip	May 1909	2½ yrs.	Died.
32	M. C.	14	Female	U. S.	Minor	Tub. hip	May 26, 1907	3½ yrs.	Died.
33	J. P.	6	Female	U. S.	Minor	Pott's disease	June 1909	7 yrs.	Still wearing jacket.
34	P. D.	3	Male	U. S.	Minor	Pott's cervical; tub. ankle	June 1909	9 yrs.	Still wearing jacket and ankle cast.
35	L. B.	3	Female	U. S.	Minor	Upper dorsal, Pott's	July, 1909	3 mos.	Died Oct., 1909.
36	W. M.	18	Male	U. S.	Minor	Tub. knee, right	Aug. 31, 1909	9 yrs.	Cured.
37	K. S.	8	Female	U. S.	Minor	Tub. coxitis, right	Oct. 1909	2 yrs. 7 mos.	Died May, 1911.
38	D. A.	2½	Female	U. S.	Minor	Lumbar, Pott's	April, 1910	4 mos.	Died Aug. 16, 1910.
39	H. M.	15	Male	U. S.	Minor	Pott's disease, knee and wrist	When a small boy	6 yrs.	Died Oct. 29, 1911, at 16 yrs.
40	T. B.	2	Male	U. S.	Minor	Pott's disease; lower dorsal.	Feb. 1909	6 yrs.	Cured.
41	M. P.	3	Male	U. S.	Minor	Hip disease, right	Oct. 21, 1910	6 yrs.	Cured.
42	N. B.	16	Female	U. S.	Minor	Hip disease	When a small child	16 yrs.	Died at 21 yrs., general tub.
43	M. S.	2	Male	U. S.	Minor	Pott's disease, dorsal	1911	7 yrs., in bad shape	Still under treatment.
44	A. S.	..	Female	U. S.	Minor	Tub. coxitis, left		10 yrs.	Cured.
45	F. W.	12	Male	U. S.	Minor	Dbl. coxitis	May 1911	1 yr. 8 mos.	Died Jan. 25, 1913.
46	J. B.	10	Male	U. S.	Minor	Tub. coxitis, right	1911	4 yrs.	Cured.
47	L. D.	9	Female	U. S.	Minor	Sacroiliac	1910	3 yrs.	Cured.
48	J. T.	3	Male	U. S.	Minor	Tub. coxitis, right	1911	4 yrs.	Died.
49	S. M.	3	Male	U. S.	Minor	Pott's disease	Aug. 1, 1911	1 mo.	Died Sept. 2, 1911
50	J. D.	3	Male	U. S.	Minor	Pott's disease	1910	2 yrs.	Died Dec. 1912.

Of those treated with tuberculin, five are still under treatment.

Unfortunately we have no records of the weight of the patients treated without tuberculin, and in only a few of those treated with tuberculin was the weight properly observed. Of these a few seem worthy of notice. We see from Table II that No. 37 gained 10 pounds in a month and two days after tuberculin was begun and has gained 21½ pounds in all.

No. 42 gained 6¼ pounds in three weeks after tuberculin treatment was instituted, although he finally succumbed to advanced tuberculosis and the mixed infection which accompanies it.

No. 43 gained 12½ pounds under treatment. He recovered.

No. 39, a little boy 3½ years old, gained in ten weeks after treatment was begun, 5¾ pounds. He recovered.

No. 45 gained in three months 17¼ pounds, although he died when he had been under treatment six months and one week.

No. 44 gained 5 pounds in five days after treatment was begun.

While in some cases which were not emaciated at the beginning of treatment there was little or no increase of weight, still the six cases quoted seemed to show that tuberculin, even in cases where it finally loses its remedial efficiency, is a powerful tonic, at least, when first administered.

It will be observed that of the fatal cases in Table II, 4 were advanced cases of pulmonary tuberculosis when tuberculin treatment was begun. Of these 3 improved temporarily under this treatment, and 2 of them probably owed several months more of life to tuberculin; although most writers on tuberculin therapy do not advise giving tuberculin, even experimentally, to such patients.

The inferences to be drawn from the figures setting forth the length of treatment and the results of treatment in the two classes are too obvious to require extended comment.

The great interest which inheres in this study will no doubt lead others to follow similar lines of investigation and leads us to promise that as our material and experience increase we shall be glad to pursue this fascinating study as far as we have the time and the ability.

The truth is mighty and will prevail and it is not unreasonable to predict that the misconception and prejudice which have confused the ra-

TABLE II.—FIFTY CONSECUTIVE CASES OF TUBERCULOSIS TREATED WITH TUBERCULIN IN THE HOME FOR CRIPPLED CHILDREN, NEWARK, N. J., THE MOUNTAINSIDE HOSPITAL, MONTCLAIR, N. J., AND IN PRIVATE PRACTICE.

No.	Name.	Age.	Nativity.	Sex.	Occupation.	Diagnosis.	Beginning of Treatment.	End of Treatment.	Remarks and Results.
1	G. M.	10	N. Y.	Female	School	Tub. left knee	Nov. 1915	Aug. 25, 1916	Knee in plaster all summer. X-Ray showed tub. March 21, 1918, perfectly well.
2	W. S. P.	29	N. Y.	Male	Clerk in store	Pulmonary tub.	April 24, 1916	Dec. 8, 1916	March 21, 1918, well after 10 mos. in sanatorium.
3	E. S.	9	N. Y.	Male	..	Tub. coxitis, left	Aug. 1915	.....	Treatment with plaster Dec. 13, 1909. Wore plaster spica 5 yrs. and 8 mos. Aug. 1915, Buck's extension, X-ray. Considerable contraction. Has improved. Walks about still wearing cast.
4	M. C.	4	.....	Female	.....	Tub. ankle	Jan. 14, 1916	.....	Perfectly well March 1918. No reactions.
5	J. H. C.	62	U. S.	Male	Druggist	Tub. of hilus	June 3, 1916	Nov. 20, 1916	Cured.
6	F. C.	9	U. S.	Male	.. ....	Cervical Pott's	Dec. 28, 1915	Sept. 28, 1916	Under treatment since 1½ yrs. old. Reported perfectly well.
7	A. W. B.	9¾	U. S.	Female	.	Pott's disease	Jan. 1915	Feb. 9, 1917	Patient fell in 1911, March. Diagnosis made Oct. 11. Legs paralyzed for 3 yrs. Wore brace and corset. Tuberculin started. Still considerably paralyzed. Spinal operation advised.
8	Mrs. E. K.	.. ..	U. S.	Female	.	Pulmonary tub.; sputum pos.	April 1917		Died after 4 mos. treatment.
9	B. K. (Daughter)	3	U. S.	Female	.	Pott's disease	March 2, 1917	.. ..	Not doing well; may require an operation.
10	H. B.	.....	.....	Male	.....	Pleuritic tub.	Oct. 17, 1916	May 11, 1917	Well; now in New York military service.
11	C. K.	5½	.....	Male	.. ..	Coxitis, l.	Nov. 26, 1915	Jan. 2, 1917	Died of tuberculous meningitis while under tuberculin treatment.
12	D. M.	7⅝	.....	Male	..	Coxitis, l.	Dec. 17, 1915	April 17, 1917	Perfectly well.
13	L. L.	..	U. S.	Male	Reßner	Lumbosacral	Nov. 27, 1916	Aug. 13, 1917	Perfectly well after 15 yrs. of illness. Tuberculin treatment lasted less than 9 mos.
14	J. B.	....	.....	Male	.....	.....	Nov. 28, 1916	Aug. 20, 1917	Discontinued treatment. General condition much improved.
15	K. C.	29	U. S.	Female	Housemaid	Tub. coxitis	Nov. 24, 1915	Feb. 13, 1917	She has suffered from hip disease since 6 yrs. old (23 yrs.). Has had several abscesses. For past 8 yrs. has been under Dr. Twinch's care. Is still wearing spica. Her general condition good. She is able to do housework.
16	I. B.	23	U. S.	Male	Moulder	Coxitis	Nov. 2, 1915	Takes nuclein with tuberculin. Less reaction.	10 yrs. ago first pain in back. Albee graft May 13. Last jacket removed Sept. 15. Under tuberculin treatment 2½ yrs.
17	V. K.	32	.....	Male	Machinist	Pott's disease	Oct. 23, 1915	April 13, 1917	No doubt of efficacy of tuberculin. Feels perfectly well. Jackets 6 or 7 yrs.
18	E. W.	28	U. S.	Male	Draughtsman	Pott's disease	April 8, 1916	Nov. 19, 1917	Died Feb. 18. Had had an Albee operation. Had nearly died in operation.
19	W. P.	15	U. S.	Male	School	Hip disease	Nov. 30, 1915	Dec. 29, 1916	Perfectly well, so far as known. Went through tuberculin treatment with only one reaction. Had had hip disease 7 yrs. Buck's extension, etc.
20	V. R. S.	10	U. S.	Male	School	Hip disease; knee	Oct. 16, 1915	April 14, 1917	When tuberculin was begun patient had been sick 2½ yrs. 2 mos. after treatment was begun, all abscesses healed and patient immensely improved. March 21, 1918, now perfectly well. All appliances and all treatment discontinued.
21	H. B.	14	U. S.	Female	.....	Tub. both knees, one ankle	March 30, 1916	Feb. 15, 1917	6 yrs. of age both knees swollen and painful. Had no treatment until 8 yrs. of age. Two operations to straighten knees by other physicians. Tub. treatment begun March 3, 1916. Nov. 19, 1917, reported well.
22	F. F.	3	U. S.	Female	.	Pott's disease	Oct. 14, 1915	April 16, 1917	Fell from bed at 14 mos. Lump developed on back. Treated intermittently. Tuberculin treatment begun. Is to all appearances well. Small discharge from sinus. Wears jacket still.
23	W. K.	5	U. S.	Male	.	Tub. coxitis	March 9, 1916	Dec. 10, 1917	Treated by private physicians, also at hospital. Tuberculin treatment begun by Dr. Twinch March 9, 1916. Patient well, but wears brace.
24	T. T.	11	U. S.	Male	.	Tub. coxitis, left hip	March 9, 1916	March 12, 1916	Treated in hospital for 6 weeks. Placed in plaster cast. Finished tuberculin treatment Reported well Sept. 6, 1917. No reaction.
25	F. T.	9	U. S.	Female	.....	Tub. knee	Oct. 14, 1915	Nov. 5, 1917	Received treatment at hospital. Abscess on one knee. Tuberculin treatment started Oct. 14, 1915. Now practically well. Still wearing cast.
26	A. R.	9	U. S.	....	.	Tub. coxitis, left hip	Feb. 24, 1916	March 26, 1917	Fell at 5 yrs. and injured one hip. Treated by osteopath. No improvement. Sent to hospital, condition improved. Buck's extension adjusted. Tuberculin treatment started Feb. 24, 1916. Finished March 26, 1917. Patient is now well. Wears no cast.
27	A. M.	6	U. S.	Male	.....	Tub. knee, left	April 27, 1916	May 10, 1917	Wore a cast for 3 mos. in hospital. Went through tuberculin treatment and was reported well March 3, 1918. Wearing cast.
28	M. J.	....	.....	Female	.. ..	Tub. right knee joint	Oct. 14, 1915	July 3, 1916	Admitted to hospital Feb. 23, 1909. Home about 6 mos. before tuberculin treatment was begun. Treatment concluded. Patient perfectly well.
29	P. Y.	....	U. S.	Male	.....	Double tub. hip	July 17, 1916	March 12, 1917	Tuberculin treatment concluded. Patient reported well. Wears no brace. X-ray taken.
30	S. C.	9	N. Y.	Male	..	Tub. right knee and ankle	March 16, 1916	July 30, 1917	Patient suffered with painful knee and ankle since 2½ yrs. old. Treated by private physicians and in hospitals. Foot amputated. Tuberculin treatment started March 16, 1916. Bismuth injections given. Much improved. Treatment ended. Still two discharging abscesses.
31	L. V.	5	U. S.	Female	.....	Pott's disease	Oct. 25, 1915	June 11, 1917	Stopped walking at age of 3 yrs. Also lost speech and hearing. Spinal operation performed in hospital in N. Y., 1914. Tuberculin treatment begun Oct. 25, 1916. Well, so far as known.

TABLE II.—*Continued*

No.	Name.	Age.	Nativity.	Sex.	Occupation.	Diagnosis.	Beginning of Treatment.	End.	Remarks and Results.
32	E. T.	7	U. S.	Female		Cervical Pott's	March 2, 1916	Nov. 27, 1916	Patient lost use of both legs at age of one year. Treated in different hospitals. Under Dr. Twinch's care bed treatment given and tuberculin treatment commenced March 2, 1916.
33	J. P.	3	U. S.	Male		Tub. ankle, glands of neck and in groin.	June 29, 1916	May 28, 1917	Developed tuberculosis of ankle at 9 mos. Two years later glands in neck and groin affected. When admitted to Home, patient had seven sinuses on ankle discharging. Also discharging glands left groin. Tuberculin treatment and bismuth injections started June 29, 1916. Neck glands returned to normal. All sinuses on ankle healed Nov., 1916.
34	M. H.	13	. . .	Female		Pott's disease	April 17, 1916	Jan. 21, 1918	Albee done 5 or 6 yrs. ago. Tuberculin treatment started April, 1916. Patient reported well. Still wearing brace.
35	C. S.	. .	. . . .	Female		. . . .	April 6, 1916	April 16, 1917	Ailing for 6 yrs. Treated by wearing spica Dec. 24, 1913. Treatment mechanical (mainly) until tuberculin was begun. Patient doing well. Wearing no cast now.
36	E. McG.	. . .	. . . .	Male		Tub. ankle	May 1, 1916	Dec. 28, 1917	Child can walk. Has cast on ankle. Has not reported in 5 or 6 weeks. Much improved by tuberculin treatment.
37	W. J. G.	44	U. S.	Male	Teacher	Pul. tub. 1st stage, sputum pos.	June 4, 1917	May, 1918	Height, 6'2¼". Weight June 16, 146⅝ lbs. April 18, 168. Cured. Chest expansion, 4 ins. No physical signs. No bacilli. Sputum examined several times.
38	T. C.	26	Swede	Female	Domestic	Tub. left thich and left sacroiliac joint	April 9, 1917	May, 1918	127 lbs. Cured. Has been actively at work for several months. Had been treated without efficacy, rest, corset, etc., for several months before April, 1917.
39	P. P.	3½	U. S	Male	None	Tub. of post-thoracic gland. No physical signs.	March 9, 1917	May, 1918	Height 3'2" March 9, 1917. 3'4½" May 25, 1917. Weight 30¾ lbs. March 9, 1917. Well. Grew 2¼ ins. and gained 5¾ lbs. in 2 mos. 25 days after tuberculin was begun.
40	T. P.	28	U. S.	Female	Auditor	Latent tub.; tonsillitis, enlarged cervical glands.	March 9, 1917	May, 1918	Height 5'6¼". Weight, 118 lbs. Well.
41	C. V.	47	U. S.	Female	Housewife	Latent tub. No signs	June 27, 1916	Sept. 18, 1917	Weight 118 lbs. April 5, 1917. Weight 122½ lbs. January 5, 1918. Well.
42	D. M.	53	U. S.	Male	Painter	Gen. pul. tub. 2nd stage. Before last illness weighed 178 lbs.; sputum always pos.	Oct. 30, 1916	Jan. 11, 1918	Weight 136¼ lbs. Gained 6¼ lbs. in 3 wks. but lost it. Died. Had been grossly intemperate and smoked 60 cigarettes a day. At first improved under tuberculin. This, however, had only a temporary effect. Condition was much improved for a considerable time by vaccines.
43	I. R.	40	U. S.	Female	Stenographer	No pos. signs, sputum negative; Pott's disease; tuberculosis.	March 11, 1916	Jan. 5, 1917	Weight 125½ lbs. Aug. 22, 1917. Well. History of tuberculosis for 26 yrs. Wore a brace 6 mos. Had three tours in sanatoria, etc.
44	W. A.	15	U. S.	Male	Clerk	Tuberculous peritonitis	Aug. 24, 1916	Nov. 3, 1917	Lost 20 lbs. in 6 wks. Under tuberculin gained 5 lbs. in 3 days. Perfectly well. Weighs now 146½ lbs.
45	H. Y.	27	Austria	Male	Farm laborer	Sputum pos. Wassermann neg. Pul. tub. both lungs	Aug. 15, 1916	Feb. 24, 1917	Patient died. Had abd. fistulae. Operated upon for tuberculous peritonitis in Feb. 1916. Wound did not heal. Under tuberculin weight increased from 103¼ to 120½ lbs. Had iritic adhesions right eye, diagnosed as syphilitic. Antispecific treatment unavailing. Had laryngeal and general miliary tuberculosis as final stage. Had taken vaccines without much effect.
46	R. V.	....	U. S.	Female	Student	Tuberculosis retroperitoneal glands. No positive physical signs.	May 3, 1916	June 2, 1917	Perfectly well.
47	M. C.	17	U. S.	Female	Housework	Pul. tub. following empyema, for which, paracentesis was done.	April 26, 1916	Nov. 16, 1916	Well July, 1918. Very sensitive to tuberculin.
48	J. S.	30	Italy	Male	Artisan	Pott's disease	Feb. 16, 1917	June 24, 1917	Well and weeking every day. Had had an Albee operation.
49	L. A.	8½	U. S.	Male	School	Tuberculous peritonitis	Aug. 9, 1917	Sept. 4, 1917	Entirely well apparently. Was sent South. Plays with spirit. Could not play at all when treatment began. Abdomen soft and of natural size instead of hard and protruberant.
50	R. D.	39	U. S.	Male	Retired	Pul. tubere. —	Dec. 11, 1917	Dec. 26, 1917	This patient had suffered from pulmonary tuberculosis for 10 yrs. Two yrs. in Adirondacks gained 27 lbs. Much better. Several months ago began to lose ground. Desired tuberculin as a *dernier resort*. After a few injections had a reaction and in two or three days afterwards, a fatal hemorrhage.

Our thanks are due to Miss Milair, the superintendent of the Crippled Children's Home, and her assistants, for valuable aid in compiling these tables, and in following up cases to determine the results.

tionale of tuberculin treatment in the minds of many of our professional brethren will be cleared away by a sufficient number of accurate and carefully recorded clinical histories of patients treated by this method.

American Origin of Syphilis.—Montesano refers to statements by Hesnaut that syphilis already existed in Italy in 1492, and by Roca that unpublished documents in Spain make the American origin theory *sub judice*.—*Il Policlinico.*

A WORD ABOUT THE DRUG TREATMENT OF NERVOUS EXHAUSTION

BY BEVERLEY ROBINSON, M.D.,

NEW YORK.

THE question of the best medication of this condition without much regard to its precise cause, is frequently a very difficult problem for the practitioner.

The ordinary tonics of iron, quinine, strychnine,

mulates the following conclusions: (1) Strictly speaking, there is no evidence for an absolute physiological minimum of fat in the diet, provided that the calorie value of the whole diet is sufficient to meet the total energy needs of the body, and to provide a surplus for fat formation in the body. (2) Practically a certain amount of fat is necessary in the diet, the alimentary canal of man having been developed to deal with a diet in which a considerable proportion of the energy is presented in the shape of fat. (3) In the diet of the infant at the breast fat gives over 50 per cent. of the total energy. (4) After weaning and for the next few years of life, up to six years of age, the main source of fat in the diet should be milk and butter. This fat should probably represent about 35 per cent. of the total energy of the diet. (5) From 6 years onwards the fat of the diet should represent from 20 per cent. to 25 per cent. of the total energy, provided that there are no excessive demands on the energy output of the body. This proportion can be increased considerably—for example, up to 35 per cent—without any deleterious effects. The proportion of 20 per cent. may be regarded as a minimum. Any increase upon this would be determined by the supplies available, it being borne in mind that fat is not only the most concentrated but also an expensive form of energy to the body. Animal fat is probably at least three times as expensive a source of energy as carbohydrates derived from vegetable sources. (6) As soon as the demands of the body become excessive—for example, 3,600 calories to 5,000 calories or more—it is unprofitable to attempt to meet the increased demands by means of carbohydrates alone, the limiting factor being probably the size and digestive powers of the alimentary tract. The proportion of fat in the diet in these circumstances should, therefore, be increased up to 30 or 40 per cent. It is a question requiring further consideration whether the energy requirements of a rapidly growing, active lad should be met in the same way by an increased proportion of fat in the diet.

The Venous Pulse.—A. Weber publishes a number of charts showing the curves of venous pulse obtained by photographic projections simultaneously with the tracings of the heart sounds. As a result of his present findings and those of his former phlebographic studies, Weber maintains the following points of view: (1) The venous pulse is the mark of volumetric variations of the veins of the neck and has nothing to do with changes in the pressure. (2) The presystolic wave, due to the auricular systole, is well known and perfectly described, and no change need be made in the notions which we already know in its respect. (3) The systolic wave is attributed by Weber to perturbation resulting from the proximity of the carotid, an opinion upheld by Mackenzie. This argument, which is very insufficient, will certainly not convince those specialists who maintain the contrary point of view. (4) The systolic aspiration of the blood in the jugular veins is due to two factors, namely, the thoracic vacuum resulting from the expulsion of the cardio-aortic blood mass, and the aspiration caused by the lowering of the auriculo-ventricular septum. In animals with the thorax opened, Weber found that the aspiration was less than before it was opened. (5) The writer looks upon the early cessation of systolic depression as a sign of beginning cardiac insufficiency. (6) The diastolic wave is attributed by Weber to a mechanism which is far from clear. It is strange that the writer does not bring forward the good arguments that he has brought forward in order to explain systolic aspiration. The changes in the diastolic wave and the positive venous pulse (Mackenzie's ventricular type) are subjected to criticism by Weber.

Glycemia in Diabetes Mellitus.—N. Roth is of the opinion that renal permeability to sugar is subject to notable individual variations. The glycemia increased during the first few days of "flour régime," only to diminish afterwards, coming to near the normal. Therefore, this glycemia offers no parallelism with glycosuria.

Scorbutus. Quinine Anaphylaxia, and Malaria.—K. Hannemann points out that the scorbutic states met with in malarial regions should, in some cases, be attributed to quinine treatment. The reality of quinine anaphylaxis is made evident by the possibility of a passive anaphylaxis, by very small doses susceptible of giving rise to typical shock. Quinine anaphylaxis has nothing whatsoever to do with medicamentous idiosyncrasy.

Continued Elimination of Bacilli Following Typhoid Affections.—Reibmayr remarks that carriers of the paratyphoid A and B bacilli react in the same way as typhoid carriers. The passage of the bacilli from the gall-bladder into the intestine is usually periodical. On the other hand, rectal elimination is generally continuous and in large quantity. The paratyphoid B organism is rarely eliminated by the kidney. Some subjects carry the organism in the throat. Most of the carriers have had at some time in their history a typhoid fever or some septic affection. The continued elimination of bacilli tends to become permanent for months or years, and about 25 per cent. of the subjects recover spontaneously during the first six months following their recovery. Cholecystitis is to be regarded rather as a result of microbic elimination than the cause. The entire number of carriers should be estimated at from 3 to 5 per cent. of those who have suffered from the disease.

A Simple Procedure for Preventing Swallowing the Tongue in Unconscious Persons.—A. Loewy and G. Meyer, by experiments on the cadaver and radiography have shown that lateral rotation of the head to the right or left appreciably increases the distance of the base of the tongue from the corresponding cervical vertebræ. The phenomenon is due to receding of the hyoid bone. The writers do not bring forward any clinical experience to prove the value of their theory and leave to others the trial of their experimental work in the field of practice.

The Neuroses of War and the Public.—A. Schüller remarks that the progress of medicine made during the present war has given splendid results, which have been greatly appreciated by the public in general. He goes on to say, however, that there is one domain against which the laity has assumed a very hostile attitude, namely, that of expert examinations and treatment of the neuroses of war. Schüller attributes this attitude to an insufficient comprehension, resulting from an absolute want of education on this subject of the masses. After a very summary exposé of the procedures of the modern neurological school, he finally ends by putting forward the following desiderata: (1) a more systematic and extended medical construction by lectures and clinical instruction at neurological services; (2) the control of excessive use of tobacco, a corrollary to the measures now in vogue for the control of alcoholism. By these measures, Schüller feels certain that a notable reduction of visceral neuroses (heart, stomach, etc.) may be obtained.

Sensibility to Magnetic Currents.—M. Kahane publishes some results of his researches on the perception of magnetic areas, the term magnetism being employed entirely from the viewpoint of physics. Just as certain organisms are particularly sensitive to the precursory phenomena of atmospheric changes, so certain individuals are more sensitive to magnetic currents. This fact is made evident by various forms of paresthesia, namely, pruritus, heat, etc. The withdrawal of the magnetic pole decreases the perception. This attains its maximum intensity in the field of the north pole of the needle of a compass. The portions of the body the most sensitive to magnetic influence are the fingerpulps, while the joints of the limbs are especially sensitive; the abdomen is more sensitive than the thorax, the head more than the trunk, to magnetic influence. The effects and therapeutic indications resulting from magnetic influence are now being studied.

Presence of a Bacillus of Gas Phlegmon on a Military Capote.—Galli-Valerio has made some researches into the germ content of the Swiss military overcoats which are dyed blue. Among many anaerobic saprophytes he found the staphylococcus pyogenes and two virulent anaerobes, viz., the *B. putrificus* or one resembling it, and one of the *perfringens* group. The author merely took bits of the cloth and sowed them in ordinary bouillon. The anaerobes could be grown in an aerobic medium along with aerobes because the latter used up all the oxygen. Controls sown only with anaerobes failed to develop cultures. One culture which contained the perfringens in abundance was inoculated into a guinea pig which developed a crepitating swelling. The latter extended rapidly and the animal succumbed in 48 hours. The autopsy showed a high degree of gas infiltration in the subcutaneous tissue. The muscles were deep red and infiltrated with fluid. A germ was found in abundance in the exudate and in the muscle which at first was not identified. It clearly had never been identified among the numerous organisms which occur in gas phlegmon. Apparently it was of the same race as the *B. chauveaui, B. welchii, B. perfringens, B. emphysematodes,* etc., etc.—perhaps the form described by von Hibler. Simonds reports having found the latter on the uniforms of the Belgian soldiers. Struck by the frequency with which shreds of cloth were found in gas gangrene wounds, he studied the uniforms and recovered a perfringens in 90 per cent. of the trench fighters. It was always associated with other germs, anaerobic and aerobic, which augmented its virulence ten thousand fold, as shown by inoculations made with pure and mixed cultures. Von Hibler showed that his anaerobe activates the tetanus bacillus.

On the Putrid Phlegmon of the War.—Nigst refers to the gas phlegmon. The latter seems to have been known to Pirogoff who recognized it as new to his day and strove to isolate it from other forms of wound infection—an edematous tumor which became gangrenous. It is under emphysema that we should look for old descriptions and for lesions in which air cannot come from the lungs or other cavities of the body. Old authors describe gas tumors of the breast, and in association with compound fractures. In such cases the gas could originate only from rapid decomposition of tissue as a result of gangrene. In 1881 Rosenbach described a bacillus in two fatal cases of progressive gangrenous emphysema. In 1882 gas phlegmons developed in typhoid patients after the injection of tincture of musk and there was recognized in the organisms found in the lesion Koch's "bacillus of malignant edema." Chauveau believed that the septic vibrion of Pasteur was the cause of these lesions. In 1886 gas gangrene in man was identified with the Rauschbrand of sheep, the germ being distinct from the bacillus of malignant edema. A small literature on gas abscess sprung up but very different conditions were comprised, as puerperal sepsis with gas phlegmon, gas tumor of the breast, etc. A new bacillus, Fraenkel's, was described, which was neither the germ of malignant edema nor of Rauschbrand. The subject now became more and more complicated as new lesions and flora were described. The b. coli was classed among the organisms which might cause gas gangrene. It seemed reasonable to believe that some one organism might play the leading role, its virulence being modified by symbiosis. The bacillus of Fraenkel or Welch was by some made the prime mover. It was not denied that the bacillus of malignant edema was able to cause these lesions in certain cases but only in mixed culture. To complicate matters, aerobic germs were found to be able to cause gas lesions. Again, gas abscesses or emphysematous infection of wounds was seen at times to pursue a benign course. It was noted that certain gas formers attacked the tissues which were rich in glycogen—muscle and liver. Generally speaking, long before the breaking out of the war there was an immense accumulation of facts concerning these gas phlegmons and gangrenous emphysema, which were in a most chaotic state. The author promises that in another article in the near future he will analyze the march of knowledge since 1914.

Correspondenz-Blatt für Schweizer Aertze

April 27, 1917.

Sick Insurance, Accident Insurance and Surgery.—Professor de Quervain writes on these subjects in view of the fact that with the present year insurance will unfold its full activity. Certain laws are now in full force, thirty-seven years having elapsed since these benefits were tentatively introduced. The author naturally considers the reaction of health and accident insurance on surgery. Health insurance has a leveling influence on the latter. The element of personal interest is abolished. A case of small surgical interest may demand an undue amount of time and pains, and thus the time and vitality of the medical man may seem wasted to him and his colleagues. Lodge practice methods are doubtless demoralizing. The practitioner does not wish to degenerate into a bureaucrat with activities chiefly clerical. He transcribes many symptoms, but not with the aim of making a diagnosis, for that will not be required beyond certain limits. He may record headache, but without any connotation of nephritis or brain tumor. A sore throat in a man who smokes and drinks goes down as chronic pharyngeal catarrh. Intercostal neuralgia imposes no obligation to look for vertebral disease. Cancer of the stomach has been masked under catarrh of the stomach or neurasthenia; cancer of the rectum by catarrh of the colon. The lodge practice custom of calling urinary disturbances catarrh of the bladder has prevented the early diagnosis of many a case of renal tuberculosis. Rheumatism, neuritis—especially sciatica—are pitfalls of the same character. The majority of painful symptoms in the lower extremities are due to traumatism. In accident insurance the government is now responsible to the worker—there is no longer a three-cornered relationship between employer, employee and insurance company. In other words, the State is the insurance company. The injured man receives 80 per cent. of his lost wages and 70 per cent. in maximum cases, of his annual earning capacity in place of the full amounts allowed under the old regime. In accident practice one must be a diagnostician, and not only of material but psychical alteration. One must in fact be a skilled neurologist to pass on the sequelæ of fracture of the skull; one must be able to make a full neurological and psychological examination in order to arrive at a correct diagnosis of the mischief done. Conditions thus differ radically from those of health insurance, where the symptom is that which causes the invalidism. In these accidents the physician has the aid of all kinds of apparatus of precision within certain limits. Measurements of all kinds and photography are used in routine. The accident surgeon must know the effects of damage to each vertebra. Rare types of fracture and dislocation will be encountered. It will be necessary to know the manifoldness of traumatisms of the elbow joint and wrist. Distortions, diastases, fracture-dislocations, subluxations, must be borne in mind. There are also traumatic forms of arthritis. The accident practitioner must also be versed in hernias. It has already been stated that a traumatic factor is at the basis of most of the affections of the lower extremities. In the knee-joint injuries to the meniscus and detachment of the cartilaginous surfaces are responsible for much disability. Petty injuries play the same role in connection with the ankle joint and metatarsus. Fracture of the calcaneus is often overlooked. The medical man has the option of treating a case with the means at his disposal or sending it to the hospital, and it is often a delicate matter to decide. The surgery of an insured man is not the same as surgery in general, for psychological differences enter into the subject. An uninsured man has every reason to get well, but an insured one may prefer the life of a pensioner to a laborer. In ordinary practice the surgeon and patient are in agreement on essentials, and this rapprochement may cause the accident surgeon to see things through the patient's eyes.

Revue médicale de la Suisse romande

April, 1918.

Traumatic Rupture of the Aortic Valves.—Reinbold states that this lesion may follow blunt violence to the

chest, a buffer accident, a long fall on the latter, and even a violent muscular effort. In other words, any of the common forms of violence may produce this accident. In 1902 de Quervain wrote up this subject and decided that the left heart was practically the one involved. In 1910 Ranelletti was able to collect 79 cases of valve rupture, and found that the aortic valves were involved in 49 and the mitral in 27. There were but 3 cases in which the right heart was involved. In mitral lesions the valves proper do not suffer as a rule, but in the aortic valves the latter must suffer *per se* as there are no pillars or chordæ tendineæ to absorb the violence. One or more valves may be torn, and the frequent association of endocardial vegetations is difficult to interpret. The author reports a personal case as follows: A man of 43 while descending a flight of stone steps slipped with both feet and tried hard to save himself. As he grasped the rail with both hands he felt a severe pain within his chest. After a little he was able to walk home, with a sense of weight in the left side. He could hear a loud murmur, and on entering his house his children heard it. The victim spent several days in bed, and was comfortable, although with sense of fatigue. After 3 weeks he resumed active life in a small way. Examined by the author 6 weeks after injury, he was thin and very pale. The cardiac impulse was low, percussion area increased to the left. There was a peculiar systolic impulse and a pronounced fremitus at the second sound, each quite distinct. An intense musical diastolic murmur was heard referable to the aortic region. This murmur was audible 60 cm. from the patient. The sphygmogram showed aortic insufficiency. Patient was otherwise quite sound. The enlargement of the heart as seen on the screen was not marked. A search was begun into the patient's antecedents with the view of discovering a predisposing cause, but the health seemed to have been perfect. He had never had rheumatism. His occupation—masseur—did not suggest any particular ailment. He was given to mountain climbing and skiing in season, and went about on a bicycle to his clients. He had been pronounced sound on several occasions, once not long before his accident. He used no tobacco and was abstemious with alcohol. Blood pressure 140, Wassermann negative, arteries soft. The force necessary to rupture a normal aortic valve has been computed as involving a certain range of blood pressure, perhaps as high as 480 mm. mercury. To rupture a chorda tendinea should require double this pressure. However, the violence was not necessarily transmitted along the bloodstream. It may have been due in part to sudden increase of intrathoracic pressure. According to Marey, if this were equal to 120-140 mm. of mercury, the degree of compression of the soft parts plus a given increase of blood pressure might be strong enough to cause the rupture. This mechanism is suggested in radioscopic work, in which sudden forced inspiration has been seen to broaden the shadow of the heart and aortic arch, as if the organs had dilated, in response to compression of the thoracic aorta. This phenomenon is seen only in undeveloped subjects, and it is conceivable that in a subject 43 years old the loss of elasticity could cause rupture in place of dilatation at the aortic orifice. As the patient carried insurance the injury had to be expertised and the proper treatment instituted.

March 30, 1918.

Fatal Injuries of the Abdominal Viscera in the Newborn.—Hedrén discusses injuries of the liver, spleen, pancreas, kidneys, intestines, and adrenals in connection with both personal finds and those in literature. The anatomy, pathogeny, and forensic aspects are alike considered. The author has seen in a personal case a parenchymatous rupture of the liver as a birth traumatism, and after spontaneous delivery, despite the current belief to the contrary. The cause of death in injuries of the pancreas and the rationale of rupture of the intestine are discussed at length. The author has seen eight cases of injury of the adrenals of the newborn, three of which followed spontaneous delivery. The fact is fully established that these visceral injuries may result purely from natural causes, although naturally more prone to occur in artificial deliveries.

Intracranial Hemorrhage of the Newborn as a Result of Birth Traumatisms.—The same author passes to a consideration of this subject, which is of great forensic importance. In 700 autopsies on newborn, unmacerated fetuses, this type of injury was found in 65, in 50 of whom labor was spontaneous. The forensic importance resulted from the fact that these births were chiefly secret. As a rule there are no other lesions either on the fetus or mother. In several the labors were rapid and easy. In 42 cases the hemorrhage was meningeal, in 5 cerebral, and in 3 both combined. Of the meningeal hemorrhages the lesion was above the tentorium in 32. Of the 50 spontaneous deliveries the child was fully developed in 23. But 3 children were actually stillborn, and the duration of the survivals was up to ten days. In most of the spontaneous cases phenomena of suffocation were present. The mechanism comprises the following factors: intracranial compression and overriding of the cranial bones and intrauterine disturbances affecting respiration and circulation, especially intrauterine asphyxia. The author does not see in congenital syphilis a notable factor in these cases, and but three cases are mentioned as surely syphilitic. Eclampsia of the mother was a factor in several cases. There are 10 recorded cases in Sweden since 1914 in which these hemorrhages were expertised in court. Of great significance is the relationship between trauma and asphyxia. Naturally the two can occur quite independently in the same subject. In case of great mechanical injury the asphyxia could be secondary to the latter. But these hemorrhages also occur in easy, rapid labors, although there is an indisposition to take the mother's unaided word in such cases. The viability of a child with one of these hemorrhages is a moot point. It is of course possible to produce a hemorrhage of violence in a sound live-born child.

Where is the Gravity Line of Man in the Upright Postures?—Hesser has established the situation of the plumbline by means of the law of equilibrium of a one-arm lever. A board is made to serve this purpose, balanced on two conical steel points. Beneath one end of the board is placed a decimal balance, in such manner that it comes in contact with a steel wedge fastened on the under side of the board. The experiment person stands on the board between the wedge and the points and the weight is read off on the scale. The distance between wedge and point and the subject's weight now being known by means of a vertical plane parallel with the steel points, the exact position is determined of the gravity line of the subject. This stands *in front* of the line of junction between the central points of the talocrural articulation. The distance between this line and the gravity line varies with changes of attitude in the body. The limits are 10 mm. and 45 mm., the individual variation being 1.5 to 2.0 cm. The gravity line runs from 1 to 1.5 cm. in front of the axis of the knee, and is very close to the axis of the hip.

Hospital Trains.—According to the Editor of *La Presse Médicale*, April 22, the German military congress met at Brussels last February and one of its features was the demonstration of a rolling hospital—a hospital train of 250 beds, vestibuled and with side entrances, provided with heat, electric light, water closets, operative car, sections for dressings, sterilization and radiography.

Criminality in Germany.—Criminality augments without cessation. To quote Socialist Mehring before the Reichstag, lying, theft, and swindling are not offset by military glories. The Bishop of Metz in his Lenten pastoral speaks of immorality, theft, and unbridled license. In Berlin in the fall of 1916 there was an average of 300 daily complaints of theft. The insecurity on the public thoroughfares is great. There are 3,000 criminals whose terms at hard labor have expired who are at large, banned alike from the public and private employ. In the Düsseldorf district in the first half of 1917 5,000 adolescents were convicted of crime, and various buildings have had to be converted into workhouses and places of detention for these persons.—*La Presse Médicale.*

Book Reviews.

THE TECHNIQUE OF PSYCHOANALYSIS. By SMITH ELY JELLIFFE, M.D. Nervous and Mental Disease Monograph Series, No. 26. Price, $1.50 net. New York and Washington: Nervous and Mental Disease Publishing Company, 1918.

THIS book answers the question so often asked by beginners in and opponents of psychoanalysis: "Where can we find an exposition of the technique of psychoanalysis?" Jelliffe has made a sincere attempt to present the principles of this practice, omitting entirely obscure theorizing and involved psychological discussion. His discussion of what patients not to analyze would obviate much criticism of the method generally made. All through the book he has stressed the individual case, giving a wealth of illustrations from his own and that of other analysts, but always emphasizing the fact that generalities are dangerous. No matter how much or how little of this book the general practitioner or the neurologist accepts, he cannot help but find much useful advice which will aid him in his dealing with neurotics.

MEDICAL SERVICE AT THE FRONT. By Lieut.-Col. JOHN MCCOMBE, C.A.M.C., and Capt. A. F. MENZIES, M.C., C.A.M.C. Illustrated. Price, $1.25. Philadelphia and New York: Lea & Febiger, 1918.

THIS little pocket volume with flexible covers which contains in the neighborhood of 30,000 words is the product of two Canadian surgeons, although the conditions described obtain everywhere on the British front. The ten chapters are devoted respectively to the front line division, the regimental medical officer, field ambulance on peace and war footings, selection of field ambulance positions, assistant director of medical services, the corps (three divisions), medical arrangemets for cavalry and casualty clearing station. Such a volume would appear to be almost a necessity for the United States medical body, although there is not the slightest intimation to that effect, unless in the selection of an American medical publishing house.

RECLAIMING THE MAIMED. A Handbook of Physical Therapy. By R. TAIT MCKENZIE, Major R.A.M.C., Professor of Physical Therapy, University of Pennsylvania. Price, $2. New York: The Macmillan Co., 1918.

THIS book comprises ten chapters devoted to the following subjects: The types of men who can be helped, medical electricity (two chapters), radiation therapy, hydrotherapy, massage, re-education, gymnastics and athletics, occupation therapy and cosmetics. The materials for the book were obtained from extensive experience among British wounded in various convalescent and orthopedic hospitals, including a number of Canadian institutions. There are 115 illustrations. The volume appears one year later than the monograph by Fox on the same subject and is much more condensed and of pocket size. Another book, by McDill, on the same subject, is an account of German practice.

MAN AND WOMAN. A Study of Human Secondary Sexual Characters. By HAVELOCK ELLIS. Fifth Edition, Revised and Enlarged. Illustrated. London: The Walter Scott Publishing Co., Ltd.; New York: Charles Scribner's Sons, 1917.

A COMPARISON of the fifth edition of this well known work with its immediate predecessor shows that it has undergone a thorough revision. Many passages have been omitted and much new material has been added to almost every chapter; but, fortunately, the book has only been enlarged by about eighty pages. In its general plan the work remains as before. The author considers the secondary and tertiary sexual characteristics and investigates the question how far these characteristic differences are artificial, how far they are the result of tradition and environment, and how far they are really rooted in the male and female organisms. Those who have followed the trend of modern work on the endocrine glands will not be surprised to learn that, according to the most advanced views, a woman is a woman because of her internal secretions; and a man, too, is a man on account of his internal secretions. The ancient idea that a woman is a woman because of her uterus, and the later view that it is because of her ovaries, are both considered inadequate. Sexuality, the author reminds us, is a far more fundamental and ineradicable characteristic of man and woman than many have hitherto consented to believe. The work is a mine of information on the various secondary sexual differences, and the author presents the subject from the viewpoints of both psychology and authropology. A glance through the index of authors will show the wide field that has been gleaned in the preparation of the volume. The author has done well to bring up to date what has long been (for the general reader, at least) the best book on the subject. The present work is also the most generally useful of the author's numerous publications.

SYPHILIS AND THE PUBLIC HEALTH. By EDWARD B. VEDDER, A.M., M.D., Lieutenant-Colonel Medical Corps, United States Army. Published by Permission of the Surgeon-General United States Army. Price, $2.25. Philadelphia and New York: Lea & Febiger, 1918.

THIS book is of especial value because of its statistics. From cover to cover it abounds in facts, and to those who are forced by circumstances to seek out facts and incidentally wish to avoid dogma, speculation and hearsay, the volume will prove a rare boon. To say more would be superfluous, as far as the merit of the author goes. The facts cover the prevalence of syphilis in geographical areas; racial, age, sex, and other incidence; methods of transmission (incorporating all the facts accumulated by Bulalez and his successors on non-veneral syphilis); statistics of prostitution; results of prophylaxis in armies and civil life; legislation bearing on syphilis; the facts of serodiagnosis and spirochete research, etc., etc.

LECITHIN AND ALLIED SUBSTANCES. THE LIPINS. By HUGH MACLEAN, M.D., D.Sc., Lecturer on Chemical Pathology, St. Thomas' Hospital, London. Price, $2.25. London: Longmans, Green & Co., 1918.

THE complex fatty bodies containing phosphorus, nitrogen, and a carbohydrate group evidently play a very important part in the metabolism of the body owing to their universal distribution in the tissues. Much of the original work on these substances was done by Thudichum over twenty years ago, and not a great deal has been added since his day; but now that the carbohydrates, the fats, and the proteins have been chemically studied as thoroughly as our present technique permits, much interest has devolved upon these complex and obscure substances, known variously as lipins and lipoids. Among these are the phosphatides—lecithin, kephalin, cuorin, and sphingomyelin—and the cerebrosides—phrenosin and kerasin. This monograph treats of these substances and related bodies and the methods of isolation and purification. Their separation is still surrounded by great difficulties, and the exact part which they play in the organism still escapes experimental analysis. Nevertheless, practically all that is known about them has been accumulated under one cover by the author, and a very complete bibliography permits of easy survey of the literature. The book will, therefore, prove very valuable to the biological chemist, and the chapter on "the lipins from a biological standpoint" should interest the physician, however little versed he may be in technical chemistry, even if his present knowledge of the subject is confined to the fact that lecithins act as antigens in the Wassermann reaction.

TYCOS GRAVITY AND TEMPERATURE TABLES FOR MINERAL OILS From Determinations of the Bureau of Standards and Other Tables for General Testing and Refinery Practice. Compiled and Edited by E. N. HURLBURT. Price, $1.00. Rochester, N. Y.: Taylor Instrument Companies, 1918.

THE first tables give the densities and temperatures each in terms of the other; these are followed by the densities, pounds per gallon and gallons per pound. Other tables give Fahrenheit-Centigrade equivalents, gauge pressure and temperatures of saturated steam, relative humidity tables, connection or flash points for barometric pressures, boiling points by altitudes, and much other like information.

Society Reports.

AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION.

Thirty-fifth Annual Meeting, Held at Boston, Mass., June 5 and 6, 1918.

THE PRESIDENT, DR. J. H. ELLIOTT, A.M.C., TORONTO, CANADA, IN THE CHAIR.

The Major Controls of the Climates of the United States.—Professor ROBERT DECOURCY WARD of Harvard University presented this communication. He stated that weather types changed from day to day and from season to season, under varying controls, and that climate was the resultant of many variables. One climate differed from another because of a different combination of controls. It was a relatively simple matter to enumerate the factors which combined to produce any given climate, but it was difficult, if not impossible, to determine the relative importance of these different controls, so intimately were they connected and so complex were their effects. The major controls of climate were the sun and latitude. The effects of these were modified by the distribution of land and water, mountain barriers, altitude, prevailing winds, ocean currents, and storms. According to the dominant control of these factors we might have continental, marine, or mountain climate. The essayist called attention to the outstanding facts regarding each of these major controls in the United States. The difference in latitude between the northern and the southern portions of the United States determined the important fact that the mean annual and seasonal, and the monthly isotherms, as a whole, showed prevailingly lower temperatures in the north than in the south. The climate of the United States was very different from what it would be were there a great transverse east and west mountain barrier. The influence of the Gulf of Mexico was much greater than it would be if such a mountain barrier existed. It would cut off the districts of the north from the warm southerly winds and from the rainfalls that now had free access from the Gulf. In discussing the effects of altitude, it was observed that altitude tempered the heat of the low lands. The local typography was also of prime importance in bringing about many modifications in climatic conditions. Among the latter the well-known mountain and valley winds were often of considerable hygienic importance in their control of the diurnal periods of humidity, cloudiness, and rainfall. In discussing the effects of ocean currents, it was shown that too much emphasis was usually laid on ocean currents as controls of climate. It should be remembered that an ocean current could have no influence on the climate of an adjacent land unless the wind was blowing on shore, and, further, that ocean waters in themselves, without the help of any ocean currents were conservative bodies and therefore tended to temper the cold or heat of any land over which their influence might be carried. A glance at the isothermal charts of the world at once showed the effects of these currents in deflecting the isotherms. In the temperate zones the weather was largely controlled by a succession of low and high pressure areas (cyclones and anticyclones), more or less irregular in their occurrence, uncertain in their duration, and differing considerably in their characteristics. Hence, weather changes were correspondingly irregular, uncertain, and diverse. Cyclones and anti-cyclones were the essential controls of climate in the latitudes of the prevailing westerly winds. It is in the detailed study of local climates that the interaction of these various controls was worked out and the part that each one played was considered.

DR. CARROLL E. EDSON of Denver said it was a matter of great satisfaction to one of the old members of this society to hear that the first paper of the program dealt with the fundamental subject which was so interesting to them. There was need of a study of our climate and more especially of our health resorts. A study of the latter would be both interesting and amusing. The influence of climate on health had not been sufficiently studied and the society was indebted to Dr. Ward for starting the study on a scientific basis.

DR. GUY HINSDALE of Hot Springs, Va., expressed his appreciation of Dr. Ward's paper on climatology and said he thought this was a subject to which more attention should be given. They should not forget that the subject of climatology had been the backbone of the work done by this society in the past. Any paper on climatology in reference to our health resorts would have a very practical application. We want to know what we are talking about when we speak of the effect of localities on health and disease. Professor Ward made one simple statement that was often forgotten, and that was that the isotherms were not at all parallel in the United States; we quite forgot the effect that altitude had upon temperature. Visitors who came from the north to the mountains further south were surprised to find it as cold in the mountains of Virginia as it was in Boston. The influence of storms, cyclones, and tornadoes on the climate was very interesting. Dr. Ward had published a very interesting article on the effect of tornadoes in the United States, in which he showed that they had a great influence in the spring and early summer, that they might occur as far north as Canada, and that the climate of New York and Massachusetts was affected by them.

DR. V. Y. BOWDITCH of Boston called attention to the great difference in climate sometimes seen within a very small radius, and cited as an example the difference in the atmospheric conditions between the coast of Maine and that of Massachusetts and Rhode Island. All were familiar with the bracing air of the Maine coast; there they had what might be called a "dry" fog, and not the drenching, wet, warm fog that they experienced on the coast of Massachusetts and Rhode Island. These were conditions that should be taken into consideration in sending a patient away for his health.

DR. W. F. R. PHILLIPS of Charleston, S. C., said he was glad to meet some who were still interested in climatology. He felt that climate exerted a great influence on health, though they did not hear as much on this subject at present as they did some years ago. He believed the way to get at the truth in regard to climatology was not so much by reading papers as by making experimental observations. Some years ago he had endeavored to impress on them the need of climatological laboratories. If they were to make progress they wanted facts and not a mere discussion of meteorological data. His purpose in speaking was to urge investigation as to the effect of climate on the human organism.

CAPT. J. H. ELLIOTT of Toronto called attention to a little book of Dr. Ward's on climatology, and emphasized the necessity of men working in health resorts being familiar with climatology. There was no question that a great deal of their knowledge of climatology and of the relation of climate to disease was empirical. By a observation of climatic conditions in connection with clinical observations in various centers we might arrive at some definite conclusion as to the effect of climatic conditions on disease processes in the body. He hoped they would have more papers in years to come on the relation of climate to health and disease.

PROFESSOR WARD, in closing, said the last point brought up was interesting. The opportunity which came in the draft camps for such observation might be grasped. This would offer the opportunity of making observations on a large body of men, though he did not know whether it would be practical as the men might not be stationed long enough at one place to give results of any value.

Experimental Vegetative Endocarditis.—Dr. CLEAVELAND FLOYD of Boston read this paper, in which he reported having isolated a nonhemolytic streptococcus in twenty cases of chorea. After describing the morphological characteristics of this organism, he stated that cultures injected into five rabbits produced typical endocarditis. Cultures from the hearts of these rabbits gave a pure growth of the streptococcus. Examination of control cases of acute articular rheumatism did not show this particular variety of streptococcus except in a few instances. It was present with such uniformity in cases of chorea that he felt that it bore some etiological relation to that disease. He had taken this organism from the throats of children having chorea and had injected them into rabbits, and had then taken the serum and used it as a therapeutic measure

in several cases of chorea with apparently beneficial results.

Dr. R. H. Babcock of Chicago recalled that he was one of the first to call attention to the relationship between tonsillar infection and rheumatism and endocarditis. In relation to the tonsils and tonsillectomy, he had observed that if the operator left a shred of tonsillar tissue the effect was very harmful. Rosenow's work had shown the influence of the streptococcus in other infections than those of the throat, and had recovered a streptococcus from the appendix. There was the probability that the injection of the streptococcus resulted in producing focal infection in different parts of the body, and if a child had a tonsillar infection he might have an endocarditis and he might have stomach trouble which was dependent upon an infection of the appendix. Dr. Babcock cited a striking instance of rheumatism and endocarditis following the leaving of a shred of tonsil at operation.

Captain Elliott stated that work of the kind presented by Dr. Floyd would lead to specific therapy in chorea. He referred to a paper read by Dr. George Smith and Dr. Alan Brown, describing a method by which injections of autoserum were made into the spinal canal in cases of chorea and the results were most encouraging.

Dr. Floyd, in closing, said that as one worked in the laboratory he saw how this organism at one time produced one type of disease and at another time it produced an entirely different type. From the work carried on in the hospital here the giving of serum had but little effect, except in one instance in which it produced a marked reaction. Dr. Morse thought it had very little if any effect.

Patent Foramen Ovale and Its Relation to Certain Cardiac Murmurs.—Dr. W. F. R. Phillips of Charleston, S. C., read this paper. (See page 402.)

Dr. R. H. Babcock of Chicago said he was interested in the murmurs that might be due to a patent foramen ovale in an adult, but he was more interested in regard to the route for the possible passage of emboli. It was conceivable that many patent ovale would not give evidence of their presence—for instance, those the size of a pinhead—and, furthermore, the passage was said to be oblique, which would lessen the force of the blood stream. If an open foramen ovale was going to produce a murmur it must be large enough to permit the stream of blood to set up a vibration. Again, the possibility of recognizing an open foramen ovale was very small, inasmuch as few cases came to autopsy and very few cases have been reported, so that there was little knowledge by which they could distinguish whether a murmur was due to a patent foramen ovale or to something else. Functional murmurs were very infrequent and he did not see how they were going to determine whether these patent foramen ovale had any clinical significance or not. Furthermore, there were no histories attached to these cases to throw any light on the way in which this kind of murmurs might be distinguished.

Dr. John H. Pryor of Buffalo said that the common functional murmur was systolic, and we knew little or nothing about systolic murmurs. It was assumed to be a valvular disease, but almost always, by careful study, there was found to be evidence of other heart disease which caused the systolic murmur. If we had a murmur produced by a patent foramen ovale would it be a systolic or a later diastolic murmur?

Dr. Babcock expressed his doubts as to whether a presystolic murmur could be detected, since one would have to have a pretty strong blood stream to give a presystolic murmur of this kind that could be recognized.

Dr. Cleaveland Floyd of Boston said one might find these murmurs present at one time and not at another time. If they were organic they would be constantly present, and possibly the patent foramen ovale might be a passageway for the blood at certain times, under certain conditions of stress, while at other times it would not permit much blood to pass through. For the detection of some of these questionable murmurs a man in Boston had devised an instrument which was helpful, and it would be well to develop work along this line and perhaps they might be able to detect slighter murmurs than they could at the present time.

Dr. Phillips, in closing the discussion, said that his paper was presented more to prove the point that the foramen ovale remained open to a greater or lesser extent in a large number of individuals, which was contrary to the general belief that it closed soon after birth. One physician studying with him a few years ago found a very large patent foramen ovale in doing an autopsy and expressed surprise at the finding. The speaker told him the condition was common. This decided him to examine a series of cadavers and collect statistics on this point. He thought the reason the condition was recognized more often in autopsy work at the present time was due to the method of preserving tissues that permitted of more careful and detailed study. The speaker explained the physics of the heart muscle under contraction and showed how the patent foramen ovale would be pulled open. He said he was not clinician enough to state how such murmurs as were caused by a patent foramen ovale could be distinguished, but he believed there was such a thing as a functional murmur without a physical basis behind it.

The Significance of Early Heart Lesions.—Dr. John R. Heffron of Syracuse presented this communication. (See page 404.)

Dr. Joseph H. Pratt of Boston said that while working under Dr. Mackenzie in London ten years ago he had learned the use of the polygraph and later had used this instrument in a Heidelberg clinic. Since his return to this country he had continued to use the polygraph and had tracings of about five hundred cases of cardiac disease or of cases suspected of cardiac disease. He understood Dr. Heffron to say that he regarded extrasystoles as a sign of myocardial degenerative disease. He had probably misunderstood, because he left convinced that one frequently found extrasystole or a premature contraction where there was no disease but simply an increased irritability. Dr. Mackenzie thought that extrasystoles were not a sign of cardiac disease taken by themselves. He knew from his own personal observations on patients followed for many years that it was possible to have an extrasystole without any other sign of heart disease. As to the prognostic value of pulsus alternans, Paul White of this city had made observations on a large number of cases of pulsus alternans, and the cases he had been able to follow had not lived more than one year after a permanent pulsus alternans developed. They had been taught that mitral insufficiency was difficult to diagnose. One might find a murmur at the apex and an accentuated second sound and no other evidence of disease and no enlargement of the heart, and possibly the murmur might be heard only in the recumbent position. He had a patient with these signs in whom a diagnosis of mitral insufficiency had been made. He felt that there was no mitral insufficiency present. If a patient showing these signs also had a history of rheumatism one might then suspect mitral insufficiency. The orthodiascope was an instrument which was very useful as a help in distinguishing neurosis from actual cardiac lesions. In neurotic patients it would be found that the vital capacity was normal, while all true cases of cardiac disease had a diminished vital capacity.

Dr. Babcock described a case which he thought might possibly have been one of patent foramen ovale, occurring in a young man who showed Gerhardt's signs, but nothing else, and he believed the condition was more frequent than we supposed. A systolic murmur in the second or third interspace without enlargement of either ventricle suggested the possibility of a patent duct. Dr. Babcock said he wished again to emphasize what he had said before, that ventricular extrasystole did not mean heart inadequacy by any means, particularly if it occurred at irregular times. Very frequently extrasystoles were due to a toxic condition or to the use of tea, coffee, alcohol, etc. Frequently it was found that when these extrasystoles were not organic they disappeared under exercise, and in such cases extrasystoles should not be held to mean degeneration.

Dr. Cleaveland Floyd said there was danger to the heart from other things than rheumatism, chorea, and epidemic diseases. He related a case in which a definite mitral regurgitation followed an infectious cold. He thought that we would have to recognize that many more minor ailments than we had hitherto supposed had an etiological relation to heart disease.

Dr. Elliott stated that a large Canadian life insurance company for which he was an examiner did not hesitate to accept those who had extrasystoles and nothing else. This they had been doing for some years and had had no occasion to regret it.

Rhythmical Breathing.—Dr. Irwin H. Hance of Lakewood presented this communication, in which he called attention to the great value of deep breathing. He stated that the adult or child should be taught the voluntary control of the diaphragm and the internal muscles of respiration, that the volumes or currents of air might be directed through the nares, over its floor, or into the attic, and that at will the air could expand the lower or the upper portions of the thorax. While the end of deep breathing was full expansion of the chest, it was undoubtedly true that unless the proper relation in the timing of the respiratory act was also taught and mastered much energy was wasted and a lack of coordination of the breathing with the muscular motion observed; hence, fatigue resulted not alone of the muscles, but of the nerves as expressed by rapid heart action and breathing, the result being derangement of the functioning power of other organs. Rhythm was also important. If one walked slowly no discord in rhythm was apparent, but let one run and then, unless trained to move rapidly, irregular rhythm gave way to shortness of breath and inability to continue such rapid motion. The shortness of breath was nature's way of restoring proper rhythm and prevented resulting injury to the lungs and heart. In other words, breathing should be timed to respond rhythmically to the demands made upon it; this could only be learned by practice and training. The common way was to train the various groups of muscles by setting-up exercises and let the breathing take care of itself. Were the instruction begun with rhythmical breathing all setting-up exercises would not only increase more rapidly muscular power but also the general efficiency of the whole man, brain, nerves, and all the internal organs. To breathe rhythmically one must learn absolute control of the diaphragm and the internal muscles of respiration. By avoiding all upper chest breathing one would appreciate, after a few days' practice, what the motion of the diaphragm when called upon to act voluntarily implied. Three minutes devoted to these earlier efforts four or five times daily sufficed; later more time was required. Too prolonged effort produced fatigue, diminished concentration, and tended to discouragement. Pumping of the diaphragm was practised in abdominal breathing and done by the quick, forcible contraction of these muscles during inspiration. Rhythm in diaphragmatic breathing differed from that of abdominal breathing. After describing the method of securing this breathing, the essayist stated that with the full understanding and mastery of diaphragmatic breathing one should be able, after complete full expansion of the lungs, to perform short abdominal breathing while keeping the chest fully expanded. Rhythmical thoracic breathing could be easily understood and carried out since it was the natural effort of everyone when asked to take a full, deep breath invariably to use this type of breathing. The value of this method of breathing was shown by the ability of the pupil to exercise longer and with less fatigue, and by the effect upon the heart, which often showed a slower pulse rate than when rhythmical breathing was not practised. Many years ago the writer said he heard the statement that in climbing a hill or going up stairs dyspnea could be avoided by breathing in on advancing the right foot and breathing out when the left foot was advanced. He had tried it and found that it worked not only with himself, but especially with delicate patients; this was simply rapid rhythm of breathing. For a longer rhythm one should breathe in when advancing the right foot for the third step. Besides the beneficial effect of rhythmical breathing upon the musculature and the cardiovascular system all patients had noted that their mental powers of concentration were increased. The effect upon the neurasthenic had been to increase their powers of self-control, and several had stated that in using a certain type of relaxing breath sleep could be induced in a short period of time. This was true in patients who had previously relied upon veronal. The effect on asthmatic patients had likewise been striking. For instance, in two cases of asthma, in which each patient used daily six to eight hypodermics of adrenalin, one ceased to need this relief in a few weeks and one in several months. Other patients had been able to ward off the spasmodic attacks of asthma by the muscular use of the diaphragm. The writer concluded that as physicians they could do much for the betterment of health and also of efficiency of individuals by directing their attention to the great need of physical training of the respiratory muscles at all ages.

Dr. Elliott asked Dr. Hance if he had any experience in the treatment of severe cases of asthma in older people, say between forty-five and fifty-five years of age, by this method.

Dr. Hance said he had had one man sixty years of age who inside of five or six weeks' time, by faithfully following out instructions, ceased to have asthmatic attacks at night. This man was not only distinctly asthmatic, but also had some heart disease. The results he had seen in asthma were a surprise to him. In connection with a paper read before the American Medical Association, *x*-ray pictures were shown which seemed to demonstrate that the diaphragm was practically immovable, and he had sought to investigate that point for himself. Asthma had been called a nervous disease, but in truth they knew very little about it. Some said that it was due to a spasm of the bronchi or the bronchioli, and possibly a spasm of the diaphragm might be the most prominent factor in the production of asthma, the condition of the lungs being secondary. That was what he was inclined to think, but he did not know how to prove it. After giving a demonstration of the breathing exercises, Dr. Hance said there were from fourteen to twenty types of breathing which this method of instruction made use of. One of these was the socalled spinal breathing, by which is was possible when lying down to so breath as to drive the spine against the hard surface upon which one was lying. In thoracic breathing there was a greater expenditure of energy and a greater degree of fatigue than if the rhythmical breathing were used.

Dr. John B. Hawes of Boston called attention to the fact that in rowing in races where the stroke was thirty per minute one invariably used the diaphragmatic form of breathing. The only time one could breathe was between stroke, one per stroke, so the breathing was also rhythmical in this form of exercise.

Dr. Babcock of Chicago said that for a long time he had instructed his cardiac patients in reference to diaphragmatic breathing. In diaphragmatic breathing the pushing action of the diaphragm on the blood vessels sent the blood to the upper right heart. He cited one instance of a boy with mitral insufficiency and an enormously congested liver whom he had instructed in diaphragmatic breathing, and had him carry it out several times a day, with the result that the liver diminished in size simply because by aspirating the blood from the abdominal vessels the congestion of the liver was relieved. Dr. Babcock expressed himself as rather skeptical in reference to the value of the breathing in some asthmatic cases, but said he would try it.

Dr. Phillips of Charleston said he thought Dr. Babcock had struck the physiological explanation as to the influence of deep breathing on the heart, only he should say that it was not so much by aspiration as by compulsion of the blood that the effect was produced. If one considered the condition of the mesenteric veins and that they could contain practically all the blood of the body, one could easily understand what an effect on the circulation diaphragmatic breathing might have. The only way to bring the blood up was by the action of the muscles of the abdominal wall and diaphragm, and the diaphragm was the only useful muscle in compressing the blood out of the abdominal vessels and putting into circulation blood that was stagnating in the viscera.

Antityphoid Inoculation in the Canadian Army.—Dr. George D. Porter, Capt. C. A. M. C., of Toronto, Canada, presented this communication. After calling attention to the important part played by typhoid fever in modern warfare, he said that only nine deaths from this disease had occurred in the army camps of the United States since September 21, 1917. The sick and death rate from this disease was so small as to be considered negligible both in the United States and in Canada. This wonderful improvement must in large part be attributed to compulsory inoculation against typhoid

fever, while improved sanitation and pure water supply materially assisted in the result. Inoculation against typhoid fever was compulsory in the Canadian Army. It was pointed out that any slight interruption in military training necessary from time to time was more than compensated for by the protection afforded by inoculation against typhoid. The Research Defense Society of England issued a leaflet on the protection against typhoid fever afforded by inoculation, dated January, 1915, in which it reported that among the Expeditionary Force in France and Belgium about 95 per cent. had been inoculated against typhoid fever, the annual average being about 90 per cent. The annual admission ratio was more than nine times greater among unprotected men than among the protected, and the death rate was thirty-one times greater among the nonprotected. An official British report stated that from August, 1914, to November 10, 1915, 1,365 cases of typhoid were reported among the British troops in France and Belgium, 1,150 having been verified by laboratory diagnosis. In 570 cases among the inoculated there were 35 deaths, while in 571 cases among those unprotected by inoculation there were 115 deaths. These figures showed that the mortality was two-thirds less among those who were inoculated. A report of Dr. Jules Courtmont showed that in 1,347 cases of typhoid fever 891 had not been inoculated; the mortality among these was 155, or 17.4 per cent., while of 256 cases inoculated there were only 8 deaths, making 3.1 per cent. The mortality among those inoculated only once was greater than among those inoculated twice, and the mortality among those inoculated twice was greater than among those inoculated three times. The technique used at the laboratory in Military District No. 2, Toronto, was to paint a small area below the clavicle with tincture of iodine and, after boiling the needles, syringes, and plungers, to inject 1 c.c. of the antityphoid vaccine, which equaled a dose of 500,000,000 dead bacteria (250,000,000 typhoid and 250,000,000 paratyphoid). A 5 c.c. or 10 c.c. record syringe was used and a freshly boiled needle for each inoculation. With an assistant painting on the iodine, they inoculated men, properly paraded, at the rate of three or four hundred an hour, and as the men liked to have this little ordeal over quickly they appreciated speed when the inoculations were properly done. The second dose of the same strength was given from four to ten days later, and the third dose, of double the strength, about a week later, making in all 2,000,000,000 dead bacteria. It was important to have the bottles containing the vaccine well shaken before using, and also to have the rubber stoppers painted with iodine before inserting the needles through them for withdrawing the fluid. Their vaccine was prepared at the Ontario Provincial Laboratory. The local reaction subsided within a few hours. The constitutional reaction comes on about six hours after the inoculation, consisting of malaise, headache, and slight rise in temperature, and in some cases a tendency to faintness. When the symptoms were severe enough the men were admitted to the hospital under the head of inoculation fever. They had inoculated in District No. 2, between January 1, 1915, and January 1, 1917, 58,382 men three times each, making in all 175,146 inoculations. They had had no deaths from these inoculations, and there had been admitted to the hospital for this cause only 117 cases, less than one-quarter of 1 per cent. of the men inoculated, or about one admission to every 1,200 inoculations. This record should remove any fears regarding any immediate danger from inoculation for those who were in good health. Since that time the laboratory unit had given 16,546 additional inoculations with even better results.

Dr. JOHN WINTERS BRANNAN of New York said that up to six months ago they had inoculated all the nurses at Bellevue Hospital against typhoid fever. Dr. Norris did the work and had done perhaps seven or eight hundred inoculations. He found that the women stood the inoculation better than the men. There were more men who begged to be excused from taking the second dose than there were women. They had had one instance in which a nurse, some eight months after being inoculated, came down with typhoid fever and had quite a severe attack. Why there was this one exception he did not know. They had at the present time two nurses with typhoid fever, both of whom stated that they had been inoculated before coming into their service, and now they were requiring all probationers and all graduates from other hospitals to bring certificates of inoculation or else to receive the inoculation. When he first appreciated the value of the paratyphoid vaccines he had had a triple vaccine made and started in giving 500,000,000 typhoid and 250,000,000 of each of the paratyphoids, thus giving a double dose, but not of the same organism. There were some young women inoculated in this way who, when they went into the army service, were required to be reinoculated. He at first thought this was because they did not know that he used the triple vaccines, but possibly it was because of the question with reference to the duration of immunity. Dr. Brannan referred to the experience of this country with the troops on the Mexican border, which had demonstrated the advisability of using the triple vaccine. The opinion in the army was that the immunity conferred by inoculation against typhoid fever was of two or three years' duration.

Dr. E. O. OTIS of Boston asked Dr. Porter how long he thought immunity lasted after inoculation against typhoid.

Dr. CARROLL EDSON of Denver said he had a group of engineers and field men who were laying out an irrigation scheme in Colorado, about thirty in number, vaccinated against typhoid fever because the water in the locality where they were working was open to more than suspicion and there was a great deal of typhoid fever in the vicinity. The water of the ranches was also open to suspicion, but none of the inoculated men came down with typhoid fever. It was reported that in one army cantonment there had been just one case of typhoid fever. This man was given his first injection and had an exceedingly violent reaction, more so than any man in the group. This man's history was gone into very carefully and it was found that exactly two weeks prior to receiving the injection he had left home and had drunk water in a community where there was more than an ordinary possibility of typhoid infection. His illness developed into a true case of typhoid fever, which ran a mild course after a severe onset. He probably would have come down with typhoid fever if he had not been vaccinated.

Dr. PORTER of Toronto, in reply to Dr. Otis' question, said the length of time of protection was for about one year after inoculation, and in the Canadian Army the men were reinoculated every year. In Canada they were now urging those living or working on farms to be inoculated against typhoid fever, because there were many sporadic cases on the farms. In one district they tested the wells last winter and found every well infected, and showed the advantage of inoculation in the rural districts. Dr. Porter said he felt that the practice of inoculation would spread among the civilian population and especially in the rural districts. He had never had a nurse faint from the inoculation. He thought the men in the army were often frightened by hearing the officers talk about the inoculations and that they were then more likely to faint. Regarding the giving of an inoculation to a man with latent tuberculosis, personally he would not give an inoculation to a person with latent tuberculosis. He did not think it was a proper procedure in a tuberculous subject, but in the army they took the men as they came and perhaps some tuberculous men were inoculated.

Five Years' Experience with Artificial Pneumothorax.—Captain C. D. PARFITT, A. M. C., Gravenhurst, Canada, presented this communication, which consisted in an analysis of seventy cases of tuberculosis treated with artificial pneumothorax. A satisfactory compression was obtained in one-half of these, while in the other one-half no pneumothorax could be induced, or it was so small that the procedure was abandoned. The abandoned cases were used as controls with which those in which satisfactory compression was obtained were compared. The results showed the advantages of pneumothorax in properly selected cases. The writer discussed a number of the complications and mishaps that might occur during this procedure.

Dr. CHARLES L. MINOR of Asheville, N. C., said that in the brief time allotted to the discussion of this paper he could not touch on the many interesting points of this question; he would therefore consider only two points. First, they had reached such a point with refer-

ence to their knowledge of pneumothorax in the treatment of tuberculosis that no man who was without this knowledge should attempt to treat tuberculosis. Every physician owed it to his patient to be familiar with this procedure. Pneumothorax in early cases of tuberculosis was not justifiable. It should be reserved for the somewhat advanced cases that refused to respond to the usual methods of treatment. In employing artificial pneumothorax some men allowed a considerable period of time, perhaps two months, to elapse between treatments, and when they came to give a treatment they would find adhesions, and possibly the treatment could not be continued. The treatment should be given more frequently, about every two weeks. The second point to be emphasized was that one should give the anesthetic time to take effect before attempting to introduce the gas. One introduced the cocaine and adrenalin into the pleura, into the intervening space, and then into the skin, and he was apt to go right on giving the injection of gas without waiting for the anesthetic to take effect. If this were done the pain would cause the patient to bear down, and as a result the lung would be pushed against the pleura, making the injection difficult. It was almost a truism now that small amounts of gas given at first were distinctly wiser than large amounts.

Dr. COLLINS H. JOHNSTON of Grand Rapids, Mich., called attention to the value of the *x*-ray both in the diagnosis of tuberculosis and as an aid to the proper conduct of the treatment. He related one instance in which both sides were involved in the tuberculous process. He collapsed one lung and then after two years collapsed the other lung. It was absurd to hope to do that successfully very often. Another case of the fulminating type was collapsed and after six months went about in fairly good condition but with his chest full of fluid. He took pneumonia and died, and at autopsy the diseased lung was found to be a mass of grissle and almost cartilaginous. As to the possibility of opening up a collapsed lung, some patients were kept collapsed for seven, eight, or even ten years. He had one patient under treatment who started his treatment in a foreign country nine years before. These cases showed how absurd it was to hold out a prospect of curing such cases in a year or two.

Dr. EDSON said he was very glad that Dr. Minor said what he did about the advantage of short intervals between treatments. He had had some experience with the procedure. In one instance, in an emergency case, in which the patient was suffering from a severe and uncontrollable hemorrhage, he employed artificial pneumothorax and the patient improved. Later he heard that Christian Science got the credit.

Dr. MINOR said he could not believe that as a general proposition it was a good thing to keep a lung collapsed indefinitely. He thought that in one or two years, varying according to the pathological condition present, it was right to attempt re-expansion of the collapsed lung. He did not think they had arrived at the point where they could say "once collapsed always collapsed."

Dr. LAWRASON BROWN of Saranac Lake, N. Y., said that Dr. Parfitt's 30 per cent. of effusions following artificial pneumothorax was better than they had done at Saranac. The question as to the length of time that a lung should be kept collapsed was very interesting. They had made an *x*-ray study of a series of cases that had been collapsed for a number of months and they found fresh tubercles, which meant that those cases should be kept collapsed for a considerable length of time. The procedure of producing artificial pneumothorax was not as easy as it sometimes appeared to be. He had had one case die of hemothorax after the operation, another case developed gangrene of the lung, and still another patient insisted on being given more gas at the time than would ordinarily have been given because it added to her comfort, and as a result the lung ruptured. It was sometimes wise to emphasize some of the unpleasant things they had all seen.

Dr. PARFITT, in closing, said that in reference to the time the lung should be kept collapsed, he thought one should be guided in this by the intensity of the process. In a case with a much contracted lung long-continued pneumothorax was desirable. Pneumothorax might also be of value in helping a patient over a critical period when he might otherwise have had an autoinfection which was prevented by contraction of the cavity. He believed thoroughly in small, frequently repeated refills, and that they should be made by aspiration rather than by pressure. The number of refills must also be decided by the way in which the lung expanded. He had perhaps not had sufficient experience to have a well founded opinion, but his procedure was not to deny pneumothorax to any one in whom it was indicated. He felt that one had to discount findings in the better lung occasionally and rely upon his judgment. Personally Dr. Parfitt said he regretted very much the apathy of the profession at large toward this useful procedure. It was not until 1914 that the procedure became popular in the province. It was estimated that with 5 or 10 per cent. of advanced cases of tuberculosis this procedure might be desirable. In their province they had some 8,000 advanced cases of tuberculosis, and many of these should have the benefit of artificial pneumothorax.

A Study of Fifty Cases of Tuberculosis, Mostly of the Glands and Joints, Treated with Tuberculin, Compared with an Equal Number Treated Without It.—Dr. RICHARD COLE NEWTON of Montclair, N. J., and Dr. SIDNEY A. TWINCH of Newark, N. J., presented this paper, by invitation. (See page 407.)

Granular Tuberculous Conjunctivitis Treated by Instillations of Tuberculin.—Dr. R. C. PATERSON of Saranac Lake, N. Y., read this paper, in which he reported a case in order to call attention to a method of treating a subacute tuberculous condition of the conjunctiva which so far as the writer knew had not been previously employed except by Ellis and Gay, whose article came to his attention after treatment had been inaugurated. The case also demonstrated the beneficial effects of controlling focal reactions produced by tuberculin on tuberculous tissues. This patient was a young man, 23 years of age, who gave very definite symptoms of pulmonary tuberculosis and involvement of the larynx. In May, 1917, the patient first noticed that the left eye was inflamed and pain was felt in the eye and forehead. When the writer first saw the patient early in August, 1917, the inner part of the left bulbar conjunctiva and the part below the cornea were covered with pale, sluggish, trachoma-like granulations, which were also present on the conjunctival surfaces of both eyelids, especially the lower. There was some injection of the conjunctival vessels; no ulceration was present. Cultures from the conjunctival sac revealed staphylococci, and a large Gram positive bacillus. The condition failed to respond to the ordinary eye washes and astringents, and with the approval of Dr. E. R. Baldwin, who agreed that the condition was probably tuberculous, two drops of a 0.00001 dilution of old tuberculin were instilled directly into the left conjunctival sac. No reaction followed this and five days later two drops more of the old tuberculin were again instilled. After four doses of the old tuberculin were thus administered at four-day intervals, two drops of a 1 per cent. solution of old tuberculin were instilled into the left conjunctival sac. This was followed by a sharp local reaction. The reaction passed off by the end of forty-eight hours; the conjunctiva then appeared clearer and the granulations were smaller than before the treatment. Ten days later a similar dose of tuberculin was instilled and almost immediately a dilatation of the conjunctival vessels could be seen and a sharp reaction followed as in the former instance. This treatment was continued for six doses at about ten-day intervals, making in all eight treatments with reactions, after which the conjunctiva showed little evidence of disease. All symptoms had disappeared at the time of writing. The lung and throat condition were quiescent during this treatment and were not affected by these reactions. The writer discussed the various forms of tuberculosis of the conjunctiva, the nature of the tuberculin reaction, and how tuberculin aided in the cure of tuberculosis. He reiterated the statement that tuberculin had no deleterious effect on normal animals; that the presence of anatomic tubercles altered the body in some way so that all the tissues acquired a hypersensitiveness to tuberculin, which disappeared when the tuberculous focus was completely healed or removed from the body; that tuberculin acted specifically on tuber-

culous foci themselves, causing an acute inflammation in and around them. These focal reactions might be seen in experimental animals, killed during a general tuberculin reaction, and also were observed clinically in cases of tuberculosis in which the disease was capable of direct observation, as in laryngeal and skin tuberculosis. The hyperemia accompanying this focal reaction permitted of a dissemination of substances whose nature was not yet definitely known into the systemic circulation which produced what was known as the general tuberculin reaction. The focal reaction thus produced by tuberculin might be a source of danger if the reaction was so great as to lead to a dissemination of bacilli to previously healthy tissues. On the other hand, if these reactions were slight and controllable the result of the inflammation was walling off of the diseased focus by by fibrosis, which was what we knew as healing. The immediate object of the tuberculin treatment should therefore be the production of slight and controllable reactions around the focus of the disease. While this sounded simple it was not so easy in pulmonary cases, for one was dealing with a multiplicity of small foci in varying stages of development, which would be influenced differently by different doses of tuberculin. The case reported showed the beneficial results of such focal reactions and a clearing up of the granulations was noticeable after each reaction. In this case it would have been unwise to give tuberculin subcutaneously on account of the extent of the lesion in the lung, but fortunately the location of the disease in the conjunctiva permitted of direct application and direct observation of the results. Whether a non-specific irritant, which would have produced an inflammatory reaction, would have brought about similar beneficial results could not be stated or denied, as it was not tried, though there were grounds for the belief that a non-specific inflammation-producing remedy might have been equally efficacious.

Dr. ELLIOTT said that Dr. Patterson's paper on the local application of tuberculin in eye conditions recalled a number of cases that came to St. Michael's Hospital in which the eye men, after treating them for a keratitis or follicular conjunctivitis, found that they responded to bacillary emulsion or old tuberculin. He also cited cases of tuberculous peritonitis, tuberculous pyosalpynx, tuberculosis of the sternum, and chronic sinuses cases that had been cleared up by the use of tuberculin. There was another condition in which it had proved very useful and that was in bilateral tuberculosis of the kidneys.

Dr. PATTERSON, in closing, said he felt that the beneficial effects of the tuberculin were due to the effects of the local inflammatory reaction and that if one did not get this inflammatory reaction he would not get the good result that he should have from the use of the tuberculin. He hesitated to use the tuberculin in this case because of the advanced condition of the lungs. In this instance the inflammatory reaction was followed almost immedately by a clearing up of the trouble.

Dr. NEWTON stated that he began the administration of tuberculin by giving one millionth of a c.c. and then if there was a reaction it was so mild that no harm was done. He used the utmost care in all pulmonary cases. In the bone and gland cases and in the eye cases it was very easy work. One point touched upon was in reference to the too timid use of tuberculin. Used too timidly it provoked a hypersensitiveness to later doses. Tuberculin was a wonderful remedy but it had many sharp points and had to be used with a great deal of good judgment. Dr. Newton cited the case of one man who was cured of tuberculosis after two years' treatment with tuberculin. This man had four acquaintances who developed the disease at about the same time and did not have the tuberculin treatment, and all were dead. One point that must be insisted upon was that a patient after having had the tuberculin treatment must continue it until the full course of treatment was completed.

Comparative Results Obtained in the Treatment of Pulmonary Tuberculosis.—Dr. HUGH M. KINGHORN of Saranac Lake, N. Y., read this paper, in which he discussed the comparative results in the treatment of pulmonary tuberculosis: (1) By graduated labor as employed at the Brompton Hospital Sanatorium at Frimley, England; (2) by bed rest treatment; (3) rest and exercise as employed by most sanatoria. He first referred to the method of treatment of pulmonary tuberculosis by graduated labor which was systematically carried out at Frimley, England, by Dr. Marcus Paterson. He claimed that the cases treated by graduated labor at Frimley were carefully selected, only those patients being chosen who were free from fever or other constitutional symptoms, who possessed considerable vitality, and had begun to show signs of improvement. So far as possible patients with signs of limited disease were preferred. Paterson paid more attention to the phyical condition of his patients than he did to the foci or disease, and he placed great importance on the auto-inoculation which was obtained from exercise and work. These two facts the essayist said were absolutely opposed to his interpretation of the modern method of treating pulmonary tuberculosis. In his judgment the physical examination of the lungs was the only sure way that one could get a knowledge as to how the foci of the disease were acting, and it was his object to treat the focus of the disease and also the general physical condition. The writer's aim was also to avoid auto-inoculation in every way possible. Auto-inoculations were the result of congestion of the foci of the lungs, and it was just these congestions that were extremely dangerous and which we should try to avoid. Bed rest treatment had been carried out very successfully by Dr. Joseph H. Pratt of Boston. His results were obtained in the homes of the sick poor in a supposedly unfavorable climate. Supervision was maintained by the class method and there was no selection of cases. In 36 per cent. of his cases the disease was far advanced when the rest treatment was begun. Under his method of treatment, 80 per cent. of those admitted in the first stage of the disease were well and working one or two years after their discharge, as were 62 per cent. of the second stage, and 20 per cent. of the third. In the period of 10 years ending July, 1915, Pratt treated 191 patients. The condition of those patients, one to ten years after their discharge, showed very clearly that strengthening a man's muscle and improving his general condition by graduated labor was not the best way to heal the tuberculous foci in the lungs. His chart and tables showed clearly that prolonged rest leads to permanent recovery in the large proportion of cases treated. At the end of one year after discharge there were 61 per cent. of the Brompton cases and 95 per cent. of the Pratt cases well and working. At the end of the seventh year there were 23 per cent. of the Brompton cases and 70 per cent. of the Pratt cases well and working. These figures demonstrated the great value of rest treatment over labor. Pratt's figures also showed that patients who underwent prolonged and intensive rest treatment did not tend to relapse. It was the constant experience of most physicians who treated pulmonary tuberculosis at health resorts that the home treatment of the disease was frequently extremely bad. Pratt's results showed, however, that he obtained results at home by his bed rest treatment which were superior to those obtained in the same climate at the Rutland Sanatorium in Massachusetts and at the Massachusetts State Sanatorium. His results were also equal to those obtained at the Trudeau Sanatorium at Saranac Lake, and at the Laurentian Sanitarium at Ste. Agathe des Monts, P. Q., Canada. The Rutland Sanatorium, though limited to favorable cases, had less than 25 per cent. of its patients well and working eight to ten years after their discharge, while 59 per cent. of Pratt's cases were well and working after this length of time. Among a large series of cases from Boston and the vicinity who were treated at the Massachusetts State Sanatoria, Miss Farmer found that 24 per cent. were well four to seven years after their discharge, while there were 63 per cent. of the Pratt patients well four to seven years after their discharge. A comparison of the results obtained by graduated labor with those by the modern rest and exercise treatment as employed at most sanatoria gave convincing proof that rest treatment was much superior to graduated labor treatment. The institution selected for making this comparison was the Trudeau Sanitorium at Saranac Lake and Ste. Agathe des Monts, P. Q., Quebec, Canada. In these institutions rest treatment was used

very thoroughly when indicated, but not so intensively as employed by Pratt. A further comparison of the intensive bed rest treatment employed by Pratt with the usual rest and exercise treatment, Pratt had a total of 191 patients, 56 per cent. of whom were well one to ten years after discharge. The Adirondack Cottage Sanitarium had a total of 1,929 patients and of these 63 per cent. were well one to ten years after discharge. The Laurentian Sanitarium had a total of 558 patients and of these 56 per cent. were well one to nine years after discharge. It would thus be seen that the results obtained by the intensive bed rest treatment as employed by Pratt were the same as those obtained by the ordinary treatment of rest and exercise as employed at the Adirondack Cottage Sanatarium and at the Laurentian Sanitarium. A critical examination of Pratt's bed rest treatment and the usual rest treatment showed that the two methods were practically the same. Pratt employed bed rest treatment in all his cases and the other employed it only in those cases in which it was indicated. The difference therefore was only one of degree. The results were the same.

Dr. JOHN B. HAWES of Boston said he was perfectly familar with Dr. Pratt's work and that Dr. Pratt made certain statements and comparisons with which he did not agree. He stated that his cases were not selected; they were selected in the finest sense of the word. Dr. Pratt took no patient who would not do as he was told to do and that was selection of the finest type. It was not fair to the State Sanatorium to quote Miss Farmer's figures for those patients were mostly men without intelligence and one could not expect to get the results with them that would be obtained with more intelligent patients. At Rutland they had 350 patients and only four men to care for them, one of whom devoted his time to administrative work. That left one man to care for over one hundred patients and it would be unfair to compare the results under such conditions to those obtained in Dr. Pratt's work.

Dr. V. Y. BOWDITCH of Boston said he greatly admired Dr. Pratt's work but it was unfair to make these comparisons, for three men could not do the work properly at Rutland.

Dr. PRATT said he had published two years ago in a paper read before the American Medical Association a list of cases referred to him and gave the number of applicants that refused to follow treatment, and the number was very small indeed. Most of his cases came from the Massachusetts General Hospital and in recent years he had not refused to take any case that would follow treatment; the number refused was less than ten. Furthermore, all the cases were included, even those that were dismissed from the class. Dr. Hawes had stated that the speaker was opposed to sanatorium treatment. He was not opposed to it, for it was easier to secure supervision in a sanatorium than in a home. The essentials in the treatment of tuberculosis were two things, first, supervision by a man well skilled in the treatment of tuberculosis and, second, the rest treatment. Rest facilities should be provided in all tuberculosis sanatoria. If the patients could not be put to bed they should be given comfortable Adirondack chairs.

Dr. WILLIAM LEROY DUNN of Asheville, N. C., said that for twenty years he had been inclining more and more to rest cure for tuberculosis. He had started by putting only the patients with fever to bed but as the years went on he had come to put practically every patient at rest in the beginning. From the results obtained he felt he was justified in doing this. The more the rest side was emphasized the better the results had been. Most of them had made a mistake in taking temperature as an indication for putting the patient at rest. When the patient was put to bed he realized that he had a serious piece of work on hand and then every step was an increase in his liberty and this made his course of treatment easier for him. Fighting tuberculosis was after all as much of a soul fight as a physical fight and if the patient met it in the right spirit one could do much more for him. He could not emphasize too strongly the importance of rest in the treatment of tuberculosis.

Dr. NEWTON expressed the opinion that in such a general discussion of tuberculosis the question of climate should not be altogether disregarded.

Dr. LAWRASON BROWN emphasized the importance of following up the tuberculosis patient and adjusting his home environment. He said that every patient should have six weeks in bed at first, the advanced cases a much longer time; this was important because it was the time at which the patient was likely to make bad mistakes, because he had not yet learned how to care for himself. He would like to see the society take two cottages, taking not too advanced cases, and not those that were doubtful, and then give those in one cottage the six weeks rest and treat the others without it, and he felt that they would soon be convinced of the value of the rest treatment. The cases that had the six weeks rest were able afterwards to increase their exercise more rapidly than those who did not have this advantage.

Dr. PHILLIPS also emphasized the value of the rest treatment for tuberculosis.

Dr. HANCE called attention to the fact that patients who stopped talking improved more rapidly than those who used their voices.

Dr. ELLIOTT further emphasized the advantages of rest and said he would put patients to bed, not six weeks, but three or six months, or a year, until they had an abacillary sputum.

Dr. KINGHORN, in closing, referred to a series of x-ray pictures to which his attention had been called which showed the changes that occurred in the lungs after rest in bed. The *x*-ray pictures showed that there was a remarkable clearing up of the lungs after absolute rest in bed. It was a great mistake to tell the tuberculosis patient to exercise until he began to feel tired; they did not tell a well man to exercise until he was played out. It had been the observation of many men who were students of tuberculosis that over fatigue might cause a relapse. He felt very strongly that the rest treatment was superior to graduated labor.

The Voluntary Medical Service Corps.—Dr. WILLIAM DUFFIELD ROBINSON of Philadelphia made a brief address in which he described the way in which this branch of service had been formed and urged all those not eligible for the Medical Reserve Corps to join it. He explained that there was a great deal of work in the Government service that could be performed by men who were ineligible to the Medical Reserve Corps, either because they were over 55 years of age, were physically disabled, or were teaching. He pointed out that much was now being done by men in the Medical Reserve Corps that could be done by older men, thus releasing the members of the Medical Reserve Corps for active duty. It had been estimated that one physician was equal to 310 men in the ranks, but it was now thought that this estimate was not sufficiently high, and that one physician was equivalent to 500 men in the ranks; if that were true of the medical officers as a whole, the men in this society with their experience and special training were worth much more than that. Possibly it would be no exaggeration to say that the value to the Army of one such man was worth 1000 men in the ranks. Dr. Robinson made an appeal to the members of the society to volunteer for this branch of the service.

Notes on X-Ray and Radium.—Dr. WILLIAM DUFFIELD ROBINSON of Philadelphia presented this communication, in which he called attention to some of the differences between the physical properties and the physiological action of radiaton of the roentgen tube and the element radium. The anode, cathode, and *x*-rays produced when a high voltage electric current was passed through a glass vacuum tube were analogous to but not identical with the alpha, beta, and gamma rays of radium. The anode and cathode rays did not pass through the glass walls of the tube and the alpha rays from the radium were cut off by a thin sheet of paper. This being true we only dealt with the gamma rays of radium, and low and high rays from a roentgen tube. Roentgen and gamma rays were very similar and produced similar reactions on living tissue. The beta rays from radium were very active but did not have great penetrating power. The highest gamma rays would penetrate lead and metal of the greatest thickness. Radiations both from radium and roentgen tubes had a selective and inflammatory action on living tissue. If given in sufficent quantity either would destroy the tissue. With radium, however, a much greater degree of reaction could be produced without

injuring healthy tissue than could be produced by roentgen rays. For this reason radium could be used therapeutically to produce greater local reaction than could be secured by the roentgen rays and it was also superior in the treatment of cancer of the uterus and rectum, and in epithelioma of the lip and mouth, or in mucous lesions. The healthy tissues through which the rays might have to pass to reach diseased tissue must not have dosage in such quantity or duration pass through it as to destroy it as well as the disease growth itself. The limit to which radium could destroy cancer cells when placed in contact with mass was a little over one inch in depth. By placing the radium or roentgen tube eight inches from the surface and treating for seven facets of entry, a tumor four inches below the surface would receive about the same radiation as any one of the seven facets of skin surface through which the rays had passed. Experience had taught that often it was necessary to use even twenty or more portals of entry to do effective work at deep points. Malignant cells were from two to five times as susceptible to the action of the rays as the normal tissue cells. This worked out all right with the roentgen rays but no one was in possession of sufficient radium to place it eight inches from the surface and treat the diseased areas a reasonable time. For this reason when a tumor was as much as one and one-half inches from the surface the *x*-ray was the preferable selection to make to secure the radiation. When radium was used the depth of its effect in the tumor must be kept well in mind. Care should be taken that the destruction of the part affected and very adjacent must not be associated with the deeper parts being only stimulated. This at once suggested the propriety of the deeper reaching *x*-rays being applied to the adjacent parts and near by glands so as to destroy any beginning mestastasis. Radium was the destructive force to be chosen for surface and local effects, and roentgen for larger and more remote areas. A ray was selected for each kind of cell; normal and pathologic cells reacted differently to radiation. A dosage entirely safe for muscle cells would destroy lypmphoid cells. The endothelium of small blood vessels was very susceptible and more so to radium than to *x*-ray. This indicated that radium was the source of radiation to be used in treating naevi and the like. Sarcoma and lymphatic glands required much less radiation than carcinoma. In malignancy radium should always be supplemented by roentgen rays, preferably from a Coolidge tube. What was most needed was to have users of radium and *x*-ray get together and standardize. The writer cited four cases in one of which, a carcinoma of the mouth, neither radium nor the *x*-ray were of avail; in the second, an osteosarcoma of the jaw, a cure was apparently effected; the third and fourth cases were inoperable carcinoma of the rectum treated successfully with radium. In both of these burns resulted from inaccurate placing and retention of the radium. Competency on the part of the attendant would have prevented these. The usual orderly or nurse had had little instruction in the effects of radium or the *x*-ray. This was an unfortunate deficiency which should be corrected before they have charge of the use of these agencies.

President's Address.—Late Results of Gunshot Wounds of the Chest.—Captain J. H. Elliott made this presentation, which he said he thought would be more interesting than the stereotyped presidential address. He described a number of gunshot wounds of the chest, showing the end results that were obtained and illustrating his talk with lantern slides. He said he could not give a better idea of what he wished to convey as to the end results in gunshot wounds of the chest than to quote an excerpt from the history of a typical case. This man was wounded on May 18, 1917, by a shrapnel fragment which entered at the internal angle of the left scapula, traversed the chest and was found at the level of the third costal cartilage. He was admitted to the hospital in collapse and had considerable hemorrhage. His case was viewed as hopeless. He had a high temperature, rapid pulse, and some delirium. There was some discharge of fluid and sticky blood from the opening. A drainage tube was introduced and the suction apparatus employed. The patient vomited and his pulse went to 106° F. A culture of the fluid discharged showed the *bacillus perfringens*, the gas bacillus, and other organisms. The patient was given digitalis and strychnine and a few days later the suction was removed and a smaller tube put in. Three weeks later he had a hugh edema of the left arm and a part of the back. The sinus was kept open and a large amount of pus was evacuated. The *x*-ray showed collapse of the right lung. When seen in Toronto, eleven months later, the only thing he complained of was pain in his right side on exertion. This case was illustrative of the desperate condition of these men after some of these injuries of the chest. The prognosis must, however, be fairly good for many men who had had chest injuries were returned to the firing line on the other side but in Canada they did not return a man to the front line after a chest injury. The surgical treatment of thoracic injuries was interesting but the speaker said he would not dwell much on that except to say that the surgeons now had no more hesitation about going into the pleural cavity than into the abdominal cavity and they did not hesitate to go boldly into the lung for a foreign body, or to amputate a piece of lung. The *x*-ray pictures shown were all taken from four or five months to a year or more after the wounds were received and the men were all back at work. It was remarkable how many cases there were of empyema that had had tubes for from three to six weeks, and yet under the fluoroscope there was no interference with the movements of the diaphragm and no sinuses. Some of those with retained foreign bodies suffered a little pain and shortness of breath at times on exertion. One rather peculiar thing was shown by the *x*-rays and that was that in many of these cases the mediastinum was pushed toward the healthy side instead of toward the injured side as one would expect. Collapse of the opposite lung might occur, and in some ten or fifteen cases the collapse was found on the opposite side and not on the injured side. One of the outstanding features was the absence of fractures of the ribs. This was explained on the theory that in cases in which ribs were fractured the injuries had been so extensive and the hemorrhage so severe that all these cases died on the field. Among the complications met with in these cases were the following, collapse, unilateral or bilateral; Hemothorax, unilateral or bilateral; infarcts, pneumonia, empyema, emphysema, subphrenic abscess, and injury to the bronchi.

Dr. John Winters Brannan said that Dr. Heiser who had just returned from the other side told him that the Italians had a hospital devoted to the care of chest wounds and that they had a method of aspirating the chest which was giving wonderful results. He stated that their mortality from chest wounds was practically nil.

Dr. James Alexander Miller said that it was of interest to note that chest injuries as well as the stress and strain of military life did not light up tuberculosis as often as was supposed. Our ideas as to the effects of military life would have to be modified by the actual experiences of the war.

Cardiac Conditions That Disqualify for Army Service.—Dr. Collins H. Johnston of Grand Rapids, Mich., presented this communication, in which he stated that many men with impaired hearts were being passed by examining boards and experience in France and England showed that many such men broke down under the stress and strain of active service. A man with a dastolic murmur should be rejected. In the absence of physical signs of heart impairment, it was the practice of many to ignore symptoms. This might not always be advisable, and yet, on the other hand, it was not wise to make a diagnosis on symptoms alone. A functional murmur at the apex that disappeared on exertion might be disregarded. Those in whom valvular disease was suspected should be examined in both the standing and the recumbent position. It was advisable to exclude a man with a loud, rough, systolic murmur at the apex, transmitted to the axilla and accompanied by a thrill and accentuated second pulmonary sound, especially if there was a history of rheumatism and enlargement of the heart. A murmur at the base where there was no enlargement was not considered sufficient ground for rejection. There was some difficulty at times in recognizing a slight degree of hypertrophy, and in the last analysis the real test of military efficiency was the capacity of the myocardium to undergo exercise. A good test of the muscular capacity of the heart was to have the appli-

cant hop one hundred times. If after this the heart returned to normal within two minutes the musculature was efficient; if it took four or five minutes for the heart to return to normal there was probably some impairment. The writer discussed a form of vasomotor instability into which the mental factor entered to a great extent and quoted Mackenzie as saying that 90 per cent. of the men of this type were suffering from physical and mental exhaustion. Those who showed no physical signs except rapid pulse and high respiratory rate would be kept under observation. Of course auricular fibrillation was usually associated with rheumatism and was disqualifying.

Colonel GEORGE E. BUSHNELL said that the Surgeon General's office was finding out that the average medical man did not know much about the examination of the heart. Some had the idea that a murmur meant valvular disease and that a man having a murmur was to be rejected. The Surgeon General's office was doing all it could to raise the general professional efficiency. They were sending a certain number of men to the Rockefeller institute for special training in cardiovascular diagnosis and there was a cardiovascular specialist in every large camp and, as far as possible, one in every small camp. A man interested in cardiovascular work in the Army at the present time was offered an opportunity for learning about cardiovascular diseases such as he would not get again in this generation. Some had the idea that when the examinations were made by experts more men would be rejected than when the average man made the examinations, but just the opposite had proved to be the truth. Many more cardiac specialists were needed in the Army as well as specialists is other lines.

The Soldier and Tuberculosis.—Dr. E. O. OTIS of Boston presented this communication. (See page 47.)

What Shall Be Done with the Tuberculous Soldiers?—Dr. JAY PERKINS of Providence, R. I., read this paper. He said that in considering this problem one might ask "What constitutes a tuberculous soldier?" Was he one who presented some physical signs associated with an old healed tuberculous lesion which might be demonstrable by an *x*-ray examination, or was he a man who had tuberculosis as a disease and not merely as a past, or doubtful present, or feared future, infection? If real disease were present, was it acute or chronic, open or closed, previously known or unknown, had it been treated and was it already in a fairly stable arrested stage, or was it far advanced and apparently hopeless? The essayist warned against the making of a diagnosis based on the findings in a single *x*-ray plate. The diagnosis having been confirmed the individual case must be considered. If the case was an arrested one, no longer dangerous to others, and the man was in good physical condition, advice was all he needed. If he was a former sanatorium patient, or one who had been educated as to tuberculosis in whom the disease was inactive, he could continue to care for himself. If there was active disease, acute or chronic, needing attention, the advice given him depended upon his condition, physical and financial, and whether the condition was discovered in the draft or in the service and in line of duty. The cases with fibroid changes, but without signs or symptoms of activity, were usually at some occupation in which they were doing fairly well and should be left alone. The active cases should be removed to a hospital. In those who went to a sanatorium and were not cured, one must take into consideration the conditions to which they returned. It was of no advantage to send a man to an institution if he had to return to unfavorable surroundings, for in such an extent he was a menace to others and had little chance for human happiness himself. The sending of such men to a sanatorium was but prolonging their misery for a few months. The writer emphasized the importance of making the hospital for advanced cases a home. He said that it was customary to recommend sanatorium patients to out door employment after they had completed their course of treatment. Often these employments necessitated heavy physical labor and too much exposure. Light indoor work was better for them. In California they had been putting these patients to work at pottery and similar handicrafts. If the tuberculosis was acquired in the line of duty the man should have some oversight. He should be referred to his home tuberculosis society or a Red Cross worker by preference. Delay in the discharge of such cases should be remedied. If the man had acquired his tuberculosis in the line of duty he should have his choice of a discharge or a Government sanatorium. Most men took the discharge. Of the men in whom a diagnosis of tuberculosis was made in the French army, only about 20 per cent. were found later actually to have the disease and the same held true in our army. There should be provision for part time work for those who had recovered from tuberculosis.

Colonel GEORGE E. BUSHNELL, in referring to Dr. Otis' statement that rules were a handicap to the expert, said that the majority of those making examinations had found the rules most useful and had found it necessary to standardize the rules still further. The rules they were using had been formulated by the best internists, and further suggestions were always welcome. In considering the question of the rejection of those suspected of having tuberculosis, the rules advised the rejection of those having lesions of "considerable extent." This was rather indefinite and some one had suggested that they specify that lesions extending to the third rib should be rejected. He felt that the intensity of the lesion was of quite as much importance as the extent of the lesion and that a very definite change at one point was of more importance and a diffuse fibrosis. He felt that a man who was harboring many tubercle bascilli had a narrower margin of safety than the man who had a fibrous lesion, even though the lesion were of some extent. There was also no doubt that many cases were wrongfully rejected and in this respect the local boards had been more liberal than he would have been. It was the borderline cases that were puzzling. Many men with slight lesions were strong athletic men and it was difficult to predict how they would stand the strain of military life. Often these apparently strong athletic men were the first to succumb because they did not take care of themselves and it was a difficult thing to gage the resistance of a man. If they disqualified all old healed tuberculosis cases as unsuitable they would have no army. The question of taking care of men who developed tuberculosis in France had been considered, and it was thought best to bring them back to this country for treatment. He felt that the climate of the Rocky Mountains was more favorable for them than that of Europe.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Wednesday, May 22, 1918.

THE PRESIDENT, DR. FRANK C. HAMMOND, IN THE CHAIR.

Tuberculosis from the Standpoint of the Genitourinary Surgeon.—Dr. B. A. THOMAS regarded tuberculosis of the genitourinary tract as invariably secondary to systemic tuberculosis. In speaking of "primary" tuberculosis of the kidney he referred to the part of the genitourinary tract primarily involved. Urogenital tuberculosis was said to be characterized by the fact that it masqueraded under misleading and often misinterpreted symptoms, a fact which was doubtless responsible for the astounding revelation that 90 per cent. of all patients presented symptoms of over a year's duration before consulting the surgeon, and that only 10 per cent. consulted the surgeon during the first six months of their symptomatology. That these patients were deprived of surgical treatment (alone curative) was due either to the fact that they were temporized with by treatment for protracted cystitis, without urological investigation, or that many physicians did not realize that nephrectomy was the treatment indicated. Urogenital tuberculosis the author divided into two types: (1) the urological; (2) the genital. In at least 80 per cent., constituting one-third of all surgical lesions of the kidney, this organ was primarily involved. In 12 per cent. the epididymis was the primary cause and in the remaining 8 per cent. was divided among the prostate, seminal vesicles, and uterine adnexa. Although the prostate was primarily involved in approximately only 6 per cent. of cases, it was said to be the seat of tuberculosis in at least 75 per cent of patients with urogenital tuberculosis, due to the fact that it was the foyer, exchange, or cross-

roads, as it were, between the urinary and the genital tracts. The bladder as a primary seat of tuberculosis was regarded as of such rare occurrence that its incidence was negligible. Tuberculosis of the kidney it was said usually occurred in the second and third decades of life; about 10 per cent. of cases, in Dr. Thomas' experience, occurred prior to the 20th year and 30 per cent. after the 40th year of life. Vesical irritability was said to be the predominant and earliest sign of renal tuberculosis in 90 per cent. of patients, indicating the necessity of early, complete urological examination if these patients were to receive the treatment to which they were entitled, at a time when cure was possible. Two questions of first importance raised were: (1) Is the cystitis tuberculous; (2) If so, is the tuberculosis of renal or genital origin? The importance of chromoureteroscopy (cystoscopy plus indigocarmine as a functional kidney test), *x*-ray examination, and pyelography in the differentiation of an ordinary pyogenic renal infection, tumor, and calculus was emphasized. Routine ureteral catheterization of a normal ureter in the presence of tuberculous cystitis, as a matter of diagnostic necessity was to be unreservedly deplored because chromoureteroscopy was all-sufficient for the best management of such cases, and was devoid of erroneous results incident to dependence upon ureteral catheterization, and particularly the possibility of the infection being conveyed to the healthy kidney. Nephrectomy with an immediate mortality of less than 5 per cent. and with a promise of 80 per cent. of cures for a period of at least three years, as contrasted with 80 per cent. of deaths inside of two and a quarter years by medical and palliative procedures was strongly recommended in qualified cases as the treatment par excellence for tuberculosis of the kidney. In genital tuberculosis of either the testicle, prostate, or seminal vesicles, treatment was said to rest between operative intervention and palliative treatment along antituberculosis lines, including tuberculin, with a definite inclination toward conservatism.

Tuberculosis of the Peritoneum.—Dr. F. HURST MAIER stated that the Mayos in 6,000 laparotomies had found some form of tuberculosis of the peritoneum in 4 per cent. of the cases and that its occurrence was in the ratio of four cases in women to one in men. The greater frequency in women they attributed entirely to infection of the Fallopian tubes. In children there was no marked sex proclivity. Tuberculous peritonitis was said to be almost always secondary to focal infection in the lungs or intestines, Fallopian tubes, or appendix. Kelly had found that the onset usually occurred during the puerperium. Three varieties, the names of which were descriptive of the pathology were: (1) Serous (ascitic), 75 per cent.; (2) Adhesive or fibroplastic, 20 per cent.; (3) Caseous or ulcerative, 5 per cent. These so-called types, however, were really expressions of different stages of development. The Mayos believed that ascites was more common in women with tuberculous tubes; while in both male and female the fibroplastic forms were relatively more common when the appendix or an ulcerated intestinal lesion had been the source of peritoneal involvement. In the early stages diagnosis was said to be practically impossible, the slight symptoms being attributed to passing functional disturbances of stomach, bowels, or reproductive organs. Only upon the manifestations of abdominal symptoms was the question of tuberculosis of the peritoneum raised. From an ovarian cyst, encysted tuberculosis of the peritoneum might be differentiated by noticing the absence of dullness in the middle line, the absence of a definite cyst wall, the more irregular outline, the more rapid growth, raised temperature. The encysted varieties had been mistaken for many abdominal conditions. The prognosis was best in the ascitic form of the disease and the most unfavorable in the caseous type. A grave prognosis was indicated in cases with particularly high temperature denoting mixed infection. In removal of diseased tubes and appendix in the operative treatment of tuberculous peritonitis care should be taken not to disturb adhesions. The Mayos had found that there were fewer relapses in those cases in which the tubes were removed, and that patients suffering from recurrent ascites after as many as four laparotomies, were cured by the removal of the primary focus; also that unless the uterus were much affected, its removal gave no better result than simple salpingectomy.

Tuberculosis from the Standpoint of the Orthopedic Surgeon.—Dr. G. G. DAVIS regarded tuberculosis as interesting to the orthopedist because of its producing cripples. The handling and treatment of cripples, he said, should be carried out only by one who had been trained and prepared to take care of that class of patients. Tuberculosis of the bones and joints was said to be a peculiar disease to the extent that it did not kill the patient quickly but disabled him. The person becoming a cripple was liable to become a charge on the community. The author asserted that communities did not care for their cripples rightly, and would not, until, as in other questions, compulsion was felt. The efficiency of the community was affected by the number of its cripples. This was seen in industrial life and while the state had taken cognizance of cripples in the industries it had not done so regarding tuberculous cripples. If tuberculosis were a preventable disease, those who could, but did not prevent it were said to be responsible. Tuberculosis of the lungs might be sudden and overwhelming but the bulk of the cases in bone and joint tuberculosis were slow, insidious and progressive. As a rule they gave ample warning that treatment might be instituted. In every community in which there were cripples from tuberculosis, as a rule, somebody was to blame for not having had them cured in time. Regarding the social treatment of tuberculous cripples it might be said that the community and the parents very often viewed them from an entirely erroneous standpoint. A cripple might be absolutely disabled; the majority were not, and were capable of doing a large amount of work. The microscope placed upon humanity would make it difficult to say who was not a cripple. Of two children in the same family, one might be a tuberculous cripple; the other have a disability of some other character; and possibly be not as bright mentally as the tuberculous cripple. Why, therefore, should the latter be pampered and given a false view of life, and the other with more obstacles punished for not studying his lessons. It was discouraging to an orthopedic surgeon endeavoring to instil ambition into a cripple educated to be self-supporting, to find such a child pampered by the parents as soon as he reached home. Such an attitude of the family toward the cripple was entirely wrong. A tuberculous cripple, like all others, should be taught self-reliance and its duties to the other members of the family and to the community. The orthopedic treatment of tuberculous cripples was of necessity carried on in institutions. For example, a child with Pott's disease should for a certain period of the treatment be confined to bed. If treatment were well carried out the case was almost certain to pursue a favorable course. Therefore, when a physician in general practice found a child with tuberculous spine, he should have it placed under hospital treatment. It was a regrettable fact, however, that the needed hospital facilities were difficult to obtain. Dr. Davis believed that the present war would make possible the proper care of chronic tuberculous patients, and draw attention to other than the acute conditions. What might be termed the strictly orthopedic handling of the tuberculous patients consisted in the local treatment and their use of apparatus. Emphasis should be placed upon the importance of preventing irritation of the local spot of the disease. To get such a patient well, however, he must be treated constitutionally. He must be given fresh air and sunlight. With the solving of the hygienic question cure of the condition was possible. This was not sufficiently appreciated.

Abuse of Milk in Young Children.—Comby would prohibit the use of more than a pint of milk daily after the completion of the first year of life while during the latter the amount should not exceed a quart daily. To subsist wholly on milk after weaning is to go without sufficient iron. The infants thus fed are anemic, fat, sluggish, constipated—in fact, really subject to a deficiency disease. The latter promptly improve upon fruit juice, purees, eggs, etc. The former alone—grape or orange juice—is sufficient for the purpose.—*La Presse Médicale.*

BLOOD CHOLESTEROL.

By AUGUST J. P. PACINI, M.D.,

NEW YORK.

PATHOLOGIST AND ROENTGENOLOGIST, MEDICAL LABORATORIES OF THE AMERICAN TELEPHONE AND TELEGRAPH COMPANY.

Conradi, in 1775, first found cholesterol in gallstones (so says Leathes in his monograph, "The Fats"). Gradually, evidence accumulated to show the presence of cholesterol in the bile, blood, brain, nerve-tissue, spleen, kidney, liver, intestine, contents of dermoid cysts, feces, meconium, sebum, epidermis, milk, and hair; and pathologically, in addition to biliary calculi, in the urine in diabetes and icterus, in the fluids of ascites and hydrocele, in tuberculous and cancerous deposits, in cataracts, atheromatous degenerations, and sometimes, in masses of considerable size, in certain cerebral tumors. But beyond recognizing the wide distribution of cholesterol in products of abnormal physiology, no record is found of especial effort directed by earlier investigators to ascertain the significance of the appearance of this important substance in pathological phenomena; and it is of striking interest that the issue which in modern times focuses attention upon cholesterol is the contention held by some observers that hypercholesterolemia is the fundamental etiological factor in the pathogenesis of cholelithiasis. Thus, after a century and a half following its discovery in gallstones, it develops that, apparently, a perverted metabolism of cholesterol is responsible for the calculus which in pathological processes it composes.

There need be no superfluous energy expended in reminding the experienced clinician of the difficulty, often the impossibility, of distinguishing between symptoms incident to gallstones, to gastric, or to duodenal ulcer. Even with the aid of every laboratory expedient, including roentgenology, many cases present where the differential diagnosis cannot with certainty be made. It is at once evident how valuable would be a definite sign, such as hypercholesterolemia, were it positively, or at least clinically reasonably pathognomonic of biliary calculosis. Henes urges that hypercholesterolemia, when arteriosclerosis, chronic nephritis, and certain other causes are ruled out, means the presence of gallstones. Other workers decline fully to subscribe to this thesis.

The desire to explore with the intention of elucidating a reason for these divergent views was the immediate stimulus to this study; and at the beginning it was clear that much confusion attended the chemical determination of the amount of cholesterol in the blood. Then it was necessary to know how the cholesterol is distributed in the blood and what factors affect its quantity, in order correctly to interpret its full significance in cases of gallstones.

A logical presentation of the subject should therefore include: (1) The technology of the determination; (2) the distribution of cholesterol in the blood; (3) the factors influencing its variation; and (4) the significance of cholesterol in cholelithiasis.

1. For a long time, the gravimetric digitonin method of Windaus was used to determine quantitatively the amount of cholesterol in a given tissue. With the advent of colorimetry, colorimetric methods were introduced by Weston, Schmidt, Autenrieth and Funk, Henes, Csonka, Gettler and Baker, Myers and Gorham, Fraser and Gardner, and Bloor. Of these methods, those of Weston and of Schmidt availed themselves of the Salkowski reaction struck by cholesterol; while the others enumerated utilized the Liebermann-Burchard reaction.

Since digitonin can combine only with free cholesterol, and cholesterol occurs in the tissues both in a free and in a combined state, preliminary saponification was a necessary measure when this method of determination of cholesterol was used. Both the free and the combined cholesterol strike either the Salkowski or Liebermann-Burchard reaction, and, therefore, in the colorimetric estimation it is not essential to saponify beforehand. Despite this truth, practically all of the colorimetric methods advanced include the unnecessarily additional step.

With blood, proper drying is a first essential. Gardner and Fraser, in 1910, suggested the admixture of a measured quantity of plaster of Paris. Myers and Gorham, in 1914, adopted a similar procedure. There is much to commend this method, but more particularly the fact that plaster of Paris contains calcium in such form that it combines with many biliary derivatives, thereby precluding the possibility of these extraneous Liebermann-Burchard reacting substances contaminating the final extract. It is not impossible that "oxycholesterol," described by Lifschutz, and similarly related substances known to contaminate the final extract when plaster of Paris is not used for drying, form the source of error indicated by Mueller.

So immediately and completely soluble is cholesterol in chloroform, that it seems impossible to desire to select any other solvent for its extraction. The mixture of alcohol and ether, offered by Bloor, is convenient, but appears to include substances which render the readings from 15 to 30 per cent. higher than the true values.

Cholesterol, at 150° C., can be distilled at ordi-

nary pressure without decomposing. The boiling point of chloroform is between 60° and 62° C. It is plainly obvious that boiling chloroform is ideally suited advantageously to extract cholesterol. Utilizing the method of reflux condensing, whereby a small volume of solvent is repeatedly extracting, as in the Soxhlet extraction of fatty portions of foodstuffs, a most desirable and efficient technique results.

Modern investigators have abandoned the Salkowski color reaction in favor of the Liebermann-Burchard test, the green color which it produces being better adapted to colorimetric estimation. An important advance has been introduced by Myers and Gorham in the choice of a permanent standard used for comparison of the unknown solution. Usually a chloroformic solution of cholesterol is employed. This readily decomposes, as Myers pointed out. The substitute offered is an aqueous solution of beta-naphthol green. Solutions of this dye appear to be permanent, and are quite easily prepared.

All the essentials just mentioned have been combined into a new method for the determination of cholesterol, as follows:

*Method of Pacini.**—One cubic centimeter of serum, plasma, whole blood, or corpuscle suspension is placed in a small porcelain crucible and mixed intimately with about 20 grams of plaster of Paris. This is permitted to dry at room temperature, or, for greater expediency, within an oven heated to not over 100° Centigrade. The dried mixture is placed in a small paper thimble, or folded into filter paper, and inserted in the carrier of a Thorn extraction apparatus. See Fig. 1.

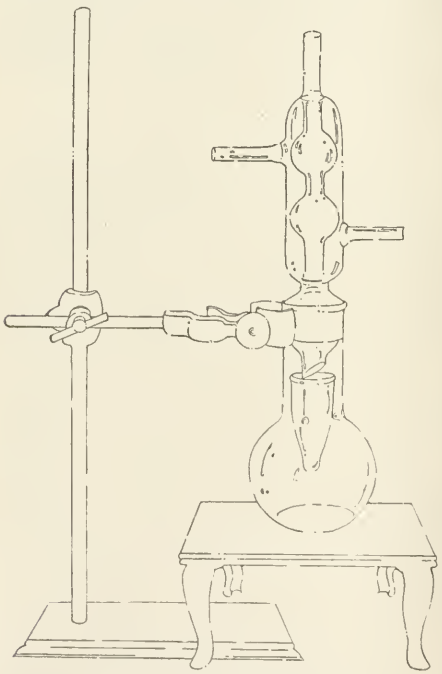

Fig. 1.—The Thorn extraction apparatus.

About 20 cubic centimeters of chloroform are placed in the extraction flask and the entire apparatus set over an electric hot plate. When the extraction has continued for one-half hour, it is complete, and is thereupon discontinued. The chloroform is permitted to cool and made to a volume of 20 cubic centimeters.

To 5 cubic centimeters of the chloroform extract are added 2 cubic centimeters of acetic anhydride and 1/10 cubic centimeter of chemically pure, concentrated sulphuric acid.

After thorough mixing by shaking, the whole is set aside in a dark place and the reaction allowed to continue for fifteen minutes. At the end of this time the color has reached a maximum and is compared against a standard, using either a Duboscq or Hellige colorimeter.

The beta-naphthol green standard is prepared by diluting 2 cubic centimeters of a 1/10 per cent. aqueous solution of the dye to 17 cubic centimeters, using distilled water.

From the Hellige reading, the cholesterol may be computed by use of the following formula:

103 minus Hellige reading, x 0.00847 = milligrams of cholesterol in 5 cubic centimeters of solution, or it may be computed from the use of the following table, copied from Myers and Gorham:

Table I.

Reading.	Mgms. in 5 c.c.	Reading.	Mgms. in 5 c.c.	Reading.	Mgms. in 5 c.c.
15	0.74	35	0.57	55	0.40
16	0.73	36	0.56	56	0.40
17	0.72	37	0.55	57	0.39
18	0.71	38	0.55	58	0.38
19	0.70	39	0.54	59	0.37
20	0.69	40	0.53	60	0.36
21	0.69	41	0.52	61	0.35
22	0.68	42	0.51	62	0.35
23	0.67	43	0.50	63	0.34
24	0.66	44	0.50	64	0.33
25	0.65	45	0.49	65	0.32
26	0.65	46	0.48	66	0.31
27	0.64	47	0.47	67	0.30
28	0.63	48	0.46	68	0.30
29	0.62	49	0.45	69	0.29
30	0.61	50	0.45	70	0.28
31	0.60	51	0.44	71	0.27
32	0.59	52	0.43	72	0.26
33	0.58	53	0.42	73	0.25
34	0.58	54	0.41	74	0.24

Of course, the value obtained either by formula or table, multiplied by four (because 20 cubic centimeters of solution was the final dilution) and again by one hundred gives the cholesterol in terms of milligrams per 100 cubic centimeters of blood (or whatever fluid was used, serum, plasma, etc.).

Attesting to the high degree of accuracy obtained when using this method, are the following data:

It will be noted that the average error is about one and one-quarter per cent. Obviously, the method is exact excepting for a negligible experimental error. To compare this method against other methods in constant use, six specimens of the same blood were analyzed simultaneously by the

*This method, based on continuous extraction with chloroform, was first demonstrated by the writer before the Brooklyn Medical Society in 1914; then before the Brooklyn Society of Internal Medicine in 1915, and in 1916 before the Bellevue Alumni Association, where it was discussed by Dr. Robert Wilson, Dr. A. B. Pacini, Drs. Epstein, Roberts, Willy Meyer, and Henes.

TABLE II.

Blood.	Cholesterol Found.	Average.	Cholesterol Added.	Theoretical Total.	Difference in Mgms.	Error, per Cent.
1. a	0.32		0.00			
b	0.32	0.32	0.00	0.32		
c	0.82		0.50

4. a	0.42		0.00			
b	0.44	0.43	0.00	0.43		
c	0.90		0.50			
d	0.94	0.92	0.50	0.93	−0.01	−1.22
5. a	0.38		0.00			
b	0.34	0.36	0.00	0.36		
c	0.88		0.50			
d	0.88	0.88	0.50	0.86	+0.02	+2.44
6. a	0.36		0.00			
b	0.38	0.37	0.00	0.37		
c	0.84		0.50			
d	0.88	0.86	0.50	0.87	−0.01	−1.22

Explanatory.—Each blood specimen, six in all, was divided into four portions, a, b, c, and d, each portion being 1 cubic centimeter. They were mixed, separately, with plaster of Paris and dried. To portions c and d of each lot was added 5 cubic centimeters of cholesterol solution, equivalent to 0.50 mgms. of cholesterol. Determinations were then made on each portion.

methods of Bloor, Myers and Gorham, Henes, and the one outlined here. Only the following summary of average percentage error incident to each method is presented, the bulk of figures entering into the results being omitted to economize space:

TABLE III—AVERAGE PERCENTAGE ERROR, SIX TRIALS, BY THE METHODS OF BLOOR, MYERS AND GORHAM, HENES, AND PACINI.

Specimen.	Bloor.	Myers and Gorham.	Henes.	Pacini.
1	+22.3	−10.0	−6.3	−1.2
2	+31.4	−18.5	−2.0	−1.2
3	+28.8	−22.5	+8.4	−0.5
4	+16.4	−14.8	−6.8	+1.2
5	+24.6	−31.6	−5.3	−1.2
6	+38.5	−11.1	−9.1	−1.2

This table is convincing of the greater accuracy of this method over the others. Owing to its relative exactness, it was chosen as the standard method for the work which follows.

2. With the advent of modern blood chemistry into medicine, many oxalated whole-blood specimens reach the clinical laboratory, where it is customary to use the whole blood for the determination of the several nitrogen fractions. In whole blood, there are 150 milligrams of cholesterol in 100 cubic centimeters of blood. Under normal conditions, this figure varies within exceedingly narrow limits, probably not less than 140 nor more than 160 milligrams. Higher figures are found when the serum alone is used, the average then being between 150 and 170, or close to 160 milligrams.

Using oxalated whole blood, or whole blood prevented from clotting through the use of hirudin, the following determinations were made upon 1, the whole blood; 2, the plasma; and 3, the washed and diluted cells.

Apparently there is generally a smaller content of cholesterol in the corpuscles than in the plasma in the proportion of 55 to 45, that is, about 55 per cent. of the cholesterol of the whole blood is contained in the plasma, the remaining 45 per cent. in the blood cells. To determine the cholesterol in the cells the whole blood is centrifuged in a graduated Purdy tube to free the plasma, which is then poured off. The cells are then made up to double their volume with isotonic saline, shaken and recentrifugalized. The saline is poured off and the cells again made up to twice their volume with fresh saline. Two cubic centimeters of cell suspension are used instead of 1 cubic centimeter of whole blood or plasma.

TABLE IV—CHOLESTEROL DISTRIBUTION BETWEEN PLASMA AND CELLS, NORMALS

Case.	Sex.	Whole Blood.	Plasma.	Washed Erythrocytes.
1	M	165	175	155
2	M	150	165	140
3	M	150	160	140
4	M	160	170	145
5	F	140	150	130
6	M	150	150	150
7	M	155	165	145
8	M	150	160	140
9	M	160	170	150
10	F	150	160	140
11	F	140	160	130
12	M	150	165	135
13	F	160	160	160
14	F	160	175	150
15	F	140	150	130
16	F	135	150	130
17	M	140	155	130
18	M	160	175	150
19	M	150	160	140
20	M	160	175	150
21	F	155	170	150
22	F	160	175	155
23	F	140	160	130
24	F	150	160	140
25	F	150	160	140

The series of normal cases presented would show that the normal distribution of cholesterol between plasma and cells is, on the average: for whole blood, 150 milligrams; for plasma, 160 milligrams; and for cells, 140 milligrams.

Recently a method has been introduced by Bloor to determine the relative proportion of free and combined cholesterol in the fractions of the blood.

Essentially, this method consists in determining the total cholesterol, then precipitating the free cholesterol with digitonin and determining the residual or combined cholesterol. By subtracting the value for the latter from the former figure, there is obtained the amount of free cholesterol. Of course, any defect in the method for determining the total cholesterol would apply to the above procedure for determining the separate fractions; and since Bloor's method is acknowledgedly erroneous in the results it yields, and the only available figures for the relative amounts of free and combined cholesterol in the blood are based upon results obtained by Bloor's method, it is plain that no accurate data are yet advanced in this particular.

There are theoretical reasons for believing that a study of the amount of free and combined cholesterol would be of practical significance to the clinician; but it seems advisable, in view of the uncertainty of the method for determining the separate portions, and because of the scant information on the topic of total cholesterol metabolism in disease, to confine attention, at least immediately, to the question of total cholesterol.

3. That the cholesterol content of the blood during the period of pregnancy presents certain varia-

tions is an opinion expressed by previous investigators. Chauffard, Laroche, and Grigaut found a hypercholesterolemia to begin about the fourth month, and progressively to increase until full term.

No other physiological processes are known which occasion hypercholesterolemia. Indeed, it is questionable whether normal pregnancy at all induces a hypercholesterolemia. In three cases of five submitted, it will be noticed that the cholesterol content of the blood does not increase during term.

TABLE V—EFFECT OF PREGNANCY ON CONTENT OF BLOOD-CHOLESTEROL

Case.	Month.									Remark
	1	2	3	4	5	6	7	8	9	
1	140	138	150	140	140	148	156	160	160	Albuminuria
2	150	140	150	150	150	145	150	150	150	Normal term
3	135	135	145	150	160	180	210	180	190	Albuminuria
4	160	165	140	155	175	175	160	165	160	Normal term
5	140	145	150	140	145	140	140	150	145	Normal term

It is significantly interesting to observe that in the cases where a hypercholesterolemia obtained there developed a nephritis during pregnancy; and that in the remaining cases, which progressed uneventfully to normal deliveries, the cholesterol content remained practically constant throughout. It may well be that hypercholesterolemia occurs in pregnancy only when complications, particularly renal, which presage hepatic changes incident to eclampsia, arise; so that hypercholesterolemia accompanying pregnancy cannot be considered a normal course, but rather a pathological sign.

Henes points out that pyrexia is a dominant pathological entity affecting the cholesterol content of the blood in that it suppresses a hypercholesterolemia, and may even occasion a hypocholesterolemia. This contention is upheld by the following laboratory evidence:

In this case, one of tertian malaria, cholesterol determinations were conducted on the whole blood, plasma and erythrocytes at intervals when it was predicted that the temperature would be highest and lowest. Striking proof of the lowering of the cholesterol content of the blood during pyrexial peaks, with return to normal values during the intervals of apyrexia, is furnished.

Certainly, chronic nephritis of such extent as to occasion nitrogen retention in the blood, particularly creatinine retention, would be expected to preclude the excretion by the impaired kidney of such a viscous colloid as cholesterol. There is, therefore, every reason to find cholesterol retention in cases of interstitial nephropathy; and reports of laboratory investigators corroborate these premises. In a series of eight cases of nephropathies incident to prostatic obstruction and showing a nitrogen retention, the following results were obtained:

TABLE VI—UREA NITROGEN, CREATININE NITROGEN AND CHOLESTEROL RETENTION IN RENAL COMPRESSION INCIDENT TO PROSTATIC OBSTRUCTION.

Case	Urea N.	Creatinine N.	Cholesterol.
1	72	2.9	190
2	36	2.6	195
3	58	1.9	170.
4	65	3.2	240
5	49	2.8	210
6	61	3.4	260

Hypercholesterolemia is said by many to occur in cases of obesity. How vague such a statement is can be inferred from the unusual complexity of classification of clinical phenomena which attends the problem of obesity. No mention is made whether the cases showing hypercholesterolemia were complicated with renal or with cardiac anomalies such as are found in some cases of obesity. No remark appears as to the type of diet customarily used in the cases wherein hypercholesterolemia appeared. So many important details are omitted as to force the conclusion that simply to state that a hypercholesterolemia occurs in obesity is without clinical or scientific meaning.

There are presented the findings in ten cases of obesity which showed no complication and which would be classified by Von Noorden as "simple obesity in otherwise healthy subjects, medium degree, body weight about 45 to 75 pounds above the average for the particular size, sex, and age of the subject."

Cases of this kind are the most frequent to present themselves for treatment, and lend themselves readily to reduction treatment.

Manifestly, in this type of obese subject, a hypercholesterolemia is not present.

Arteriosclerosis and diabetes are said to be accompanied by a hypercholesterolemia. In the course

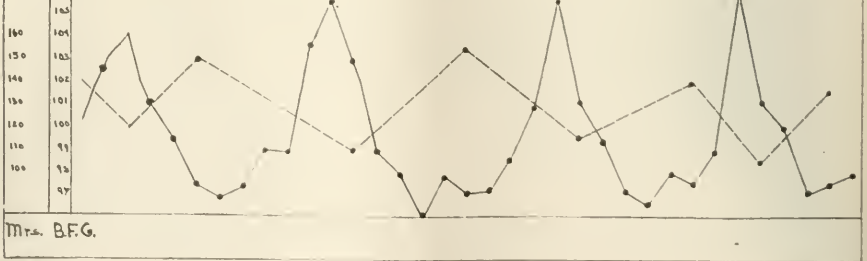

FIG. 2.—Temperature and cholesterol curves in a case of Tertian malaria; broken line, cholesterol; continuous line, temperature

of this study, eighteen cases of glycemia and glycosuria were examined and gave values for cholesterol ranging between 180 and 240 milligrams per hundred cubic centimeters of blood. But three cases of arteriosclerosis were investigated. The first showed 185, the second 190, and the third 175 milligrams of cholesterol per hundred cubic centimeters.

TABLE VII.—CHOLESTEROL CONTENT OF WHOLE BLOOD IN CASES OF OBESITY AS DESCRIBED ABOVE.

To summarize these findings it will be noted that temperature exerts a marked influence upon the cholesterol content of the blood, just as Henes contends. Pregnancy, unless complicated with intercurrent disease, does not show a hypercholesterolemia. Diabetes and arteriosclerosis give values higher than normal.

We arrive now at a discussion and study of the changes and significance of cholesterol in the blood of cases of cholelithiasis.

4. McNee demonstrated an excess of cholesterol in the bile during gestation, and Aschoff accepted this finding in support of his theory of a "cholesterol diathesis" to account for the frequency of gallstones in women who have borne children.

Together with J. T. Pilcher, the writer, in 1914, undertook a number of cholesterol determinations in the serum of some thirty cases of gallstones operatively confirmed at the Pilcher Clinic. In each instance a figure was obtained much higher than the normal; and while we at that time felt that the explanation of the etiological pathogenesis of biliary calculosis was perhaps contained in the hypercholesterolemia present in these cases, two fundamentally important factors upon which our inference was based needed more careful scrutiny.

First, the method used then for the determination of cholesterol was similar to the one described above excepting for one vital difference, the manner of drying the specimen. In our earlier work the serum was allowed to run onto a gauze pledget and there permitted to dry spontaneously.

Then the determination was conducted upon the serum, not upon the whole blood.

Let it be recalled that Henes, who strongly advocates the diagnostic value of hypercholesterolemia in gallstones, used serum for his determinations; and that Myers and Gorham, who do not fully subscribe to the stand taken by Henes, used whole blood in their study.

With these details in mind, it will be of interest to review some of the earlier findings (Table VIII):

Jaundice, as evidenced by the amount of pigmentation of the sclera, was recorded in terms of one, two, three, and four plus. No obvious coloring was denoted negative. Faint discoloration of the sclera, one plus; distinct discoloration of the sclera, two plus; marked scleral pigmentation with faint discoloration of the integument, three plus; and, plainly apparent jaundice involving both sclera and skin, four plus.

TABLE VIII.

Serum content of cholesterol in cases of gallstones, diagnosis confirmed at operation. Method for the determination of cholesterol as outlined above save for the preliminary drying of the specimen which, in this series, was accomplished without the use of plaster of Paris.

Urinary bile was tested for qualitatively in casually voided specimens, using Smith's iodine reagent. Similarly, the bile in the serum was determined by Smith's iodine test, unless the serum was so discolored as to require no further confirmation of its presence.

There is revealed in this table a peculiar tendency to greater "cholesterol-content" in those cases wherein icterus was most marked. Rather than "cholesterol-content," it were more exact to say that cases of gallstones complicated by jaundice show a higher quantity in the blood of Liebermann-Burchard reacting substances extracted by chloroform.

That cases of cholelithiasis with gall-bladder obstruction ample to occasion visible jaundice show a high cholesterol content are findings corroborative of Henes'. But it remains to be explained whether or not the excess cholesterol is due to the abnormal presence of bile in the blood.

Since calcium derivatives are particularly active in combining with many biliary derivatives, the method for the determination of blood cholesterol was modified by using plaster of Paris as a drying agent, thereby obtaining not only more rapid desiccation of the specimen, but also a means of eliminating contaminating biliary substances.

At this time a series of twelve clinically certain cases of gallstones were examined using oxalated whole blood instead of serum for the determination of the cholesterol, with these results.

Only two cases, numbers three and six, showed a hypercholesterolemia. When plaster of Paris was used for drying, the value is lower than otherwise. Manifestly, the plaster of Paris removes some product which gives a higher value than the true cholesterol reading. Equally noteworthy is the fact that all the cases of gallstones do not show a hyper-

cholesterolemia when whole blood is used for the determination.

In a separate study it was indicated that in pernicious anemia a certain characteristic partition of the cholesterol between the plasma and the cells takes place. It was shown that, (1) the whole blood content of cholesterol was diminished, (2) the plasma content of cholesterol was diminished, and (3) the cell content of cholesterol remained normal, or was even slightly increased over normal. More important than the hypocholesterolemia which is found in pernicious anemia is the altered distribution of cholesterol between the plasma and the cells.

Since Henes used serum, and the values advanced in table 9 are for whole blood; since these findings are opposite, it appeared that the reason for the discrepancy might be found in a disturbed partition of cholesterol between plasma and cells in such manner that when the plasma is utilized for the estimation of cholesterol, a higher value is obtained than when the cells or whole blood are used. That is, a change like that found in pernicious anemia in that the distribution is altered, but unlike pernicious anemia in that the cells decrease in content and the plasma increases. Were this hypothesis correct it would explain the contrary findings of Henes, who uses serum, and others, using whole blood, as to whether a hypercholesterolemia obtains in cases of gallstones.

Supporting the correctness of the hypothesis are the following actual findings (Table X):

Two generalizations are apparent from this table of findings, first, not all cases of cholelithiasis show a whole blood hypercholesterolemia; then, all cases of gallstones, at least in this series, show a relative increase of cholesterol in the plasma against a relative decrease of cholesterol in the cells.

Clinically, not all of the above cases showed symptoms of jaundice, but all applied to the clinic for relief of abdominal distress, and operation revealed the presence of gallstones, all clinical discomfort leaving the patient immediately upon recovery from the surgical procedure.

It seems unquestionable that a gall-bladder charged with gallstones might at times prevent the free elimination of bile by that viscus, and that not infrequently slight absorption of bile could result; an absorption too insignificant to produce general icterus giving objective signs, yet sufficient to cause slight hemolysis of some red cells.

That bile is a powerful hemolysin is well recognized. Slight resorption of bile would be ample to destroy sufficient red cells to occasion an increase of cholesterol in the plasma, though, of course, the total quantity of cholesterol in the whole blood remains the same.

TABLE X.

Cholesterol partition between cells and plasma in proved cases of gallstones.

35	195	210	155
36	175	195	135
37	190	215	140
38	165	180	135

Viewed from the experimental evidence submitted, the hypothesis is ventured that cases of gallstones giving clinical symptoms which bring the patient to a physician for remedy, hold an increase of bile in the blood which may be so scant as to preclude observation. To this phenomenon is given the name "occult jaundice."

Occult jaundice may be responsible for the following established findings: (1) Little or no increase of cholesterol in the whole blood; (2) a disturbed cholesterol partition between the whole blood and cells occasioning an increase in the plasma and a decrease in the cell contents.

The value of cholesterol partition in the diagnosis of cholelithiasis is obvious. Certainly, it is of greater significance than hypercholesterolemia estimated alone upon the whole blood.

145 GATES AVENUE, BROOKLYN.

Pseudoreinfection in Syphilis.—According to Hell, true reinfection is rare and hard to prove, and there are several conditions which closely simulate it. One is of course chancre redux or reinduration, in 50 per cent. of which the regional lymphnodes swell and an exanthem may appear. Chancre redux seems to be often the only remaining focus for spirochetes in the organism. The chancre-like mucous papule is like the chancre redux in all save location. A superinfection must be distinguished from a reinfection but up to the present time, the author says, no case of the former has been completely demonstrated. — *Correspondenz-Blatt für Schweizer Aerzte.*

NEURONS: THEIR RELATION TO THERAPEUTICS, MEDICAL AND MECHANICAL.

By DOUGLAS GRAHAM, M.D.,

BOSTON, MASS.

"That part of our nature which lies half-way between the body and the spirit and partakes of the nature of both: the nervous system."—Rev. George W. Field, Bangor, Maine.

THE minute anatomy of the nervous system has been so carefully studied of late years, and the theory of its functions has changed so rapidly, that but few of us older fellows have been able to alter the views that were so positively taught twenty-five years ago. And, indeed, among modern students of the nervous system, its nomenclature, structure and functions are not by any means uniform, indicating either difference of opinion or carelessness of study. For our present purpose it will be sufficient to recall a few of the recent and most generally accepted investigations in this field.

The neuron consists of the nerve cell and its branches; the latter are one or two axis-cylinders called neuraxons, and from these proceed side branches called collaterals, which end in tufts of fibrils called terminal arborizations. These terminals communicate with the shorter and more numerous processes of the cell, the dendrites or dendrons, so called from their treelike appearance. The axis-cylinders and their collaterals form the nerve fibers, and their function seems to be to convey impulses from their cells through their terminal arborizations to the dendrites of other cells which receive the impressions. For a long time physiologists firmly believed and taught that the processes of nerve cells acted by *continuity*, but more recent researches indicate that they act by *contiguity*, and not by continuity at all. But it is difficult to conceive how this can be unless the nerve cells and their processes are surrounded by a fluid medium. The neuroglia cells form an insulating material between the nerve cells, and must either be active or passive when the neurons are in contact or not in contact. According to the most authoritative histologists, the neuroglia cells are passive, but a very distinguished one, a Spaniard, Ramon y Cajal, is of the opinion that the neuroglia cells are the active agents, and that when they are relaxed their processes penetrate between the dendrites and terminal aborizations of the nerve cells and hinder the transmission of nerve currents. When the processes of the neuroglia cells are retracted, then the nerve-cell projections are allowed to come in contact. The neuroglia-cell processes have numerous short arborescent collaterals, and Cajal thinks he has observed two phases of them: one, that of contraction when the cell body augments while the processes shorten and the branches disappear; the other that of relaxation when the processes of the neuroglia cells are elongated. Hence it might appear that the movement on the part of neurons is a passive one, depending upon the interposition of the insulating material. It is more than likely that the activity of the neuron has been mistaken for the passivity of the neuroglia.

Be that as it may, it seems to be now pretty unanimously conceded that nerve cells and their processes (neurons) are distinct and separate from each other, and therefore the theory that they somehow act upon each other by contiguity and not by continuity, would seem to have some foundation. In health, when free from fatigue, these nerve-cell projections are supposed to come into contact with each other and form various combinations of feeling, thought, and action, and the machinery of life goes on when the cogwheels connect, so to speak. Having reached the limits of fatigue, their terminal arborizations and dendrites no longer come into contact by interlocking, overlapping, or however it may be, but recede from each other, and we have in the brain sleep, in the muscles relaxation, until rest brings them back to a normal condition, removes their waste products, and supplies them with nourishment, when they are again ready to respond by contact to appropriate stimuli. When we have disturbance, functional or organic, then the proper combinations of cells no longer connect for the performance of healthy voluntary or involuntary functions.

Hypnotism has been invoked to throw light upon this interesting subject.[1] The state of lethargy and relaxation induced thereby would be explained by the retraction of the neurons in the brain, so that their terminals do not connect or articulate with the dendrites of the neuhons in the spinal cord. Catalepsy would then be due to too close contact of the same, manifesting itself by an increase of muscular tone; somnambulism by the combination of certain neurons while others are retracted in sleep, and the sudden disappearance of hysterical paralysis by a removal of contact of the various nerve-cell combinations at fault.

The behavior of nerve cells and their processes, theoretically at least, would seem to be somewhat similar to that of the white blood corpuscles in their peculiar ameboid properties. Under the microscope, leucocytes anesthetized by the absence of oxygen and the presence of carbonic acid, would seem to have their pseudopods retracted. This is thought to form a basis for the histological theory of sleep, the prolongations of the nerve cells being retracted during sleep and expanding when awake; in dreams some being partially or wholly connected, while others that go to make up the conscious ego are still contracted in slumber. When we are profoundly absorbed in abstract thought we do not hear the ordinary sounds around us, for certain of our cerebral cells seem to have the faculty of breaking their communications, of somehow closing the door to obtrusive sensations.

Wiedersheim[2] observed in the *Leptodera hyalina* (a species of worm belonging to the nematods) that the nerve cells were not immovable, but presented changes of form—ameboidlike movements. He studied the living neurons in the brain of this little animal, which has so transparent a skin and body that the cells of its brain can be observed while in full activity. These cells seemed to be endowed with a wonderful degree of mobility, changing their forms, protruding their ramifications, and drawing them in, as the ameba protrudes [illegible] of being nearly [illegible] he was a small boy. pseudopods. The peripagony of it. This leads him to olfactory cells are pret[illegible]nat Simon de Montfort, during with motion, ar[illegible]ne Albigenses, put some of them to the prolongat[illegible]g the soles of their feet with a feather. may have become so tightly interlocked By fancy could not let go. Perhaps something of the kind occurs in tetanus.

clusive evidence in favor of this captivating theory that nerve cells and their projections act by contiguity and not by continuity, is that of Prof. C. F. Hodge of Clark University, Worcester, Mass. His experiments and observations, entitled "A Microscopical Study of Changes Due to Functional Activity in Nerve Cells," are given in detail in the *Journal of Morphology* for November, 1892. It is one of *the* articles of the nineteenth century, and as the journal in which it is published is accessible to but few readers, the methods and results are here produced at a length that is more worthy of them than the brief manner in which they have hitherto been referred to. The spinal-root ganglia were chosen for observation. The plan was to stimulate a nerve going to one or more of these ganglia on one side of the animal, leaving the corresponding ganglia on the other side, at rest, for comparison. The right side was always chosen for stimulation. The stimulated nerve was never divided, so that the contraction of the muscle could indicate the healthy condition of the nerve. At the end of the desired length of time the stimulated ganglion, with its mate on the other side, were excised, treated alike, and put on the same slide of the microscope. The following results are from fifteen experiments on frogs and eleven on cats. As the most instructive series is in Table IX it will be first presented. The experiments were on six cats, in which the right brachial plexus of each was stimulated by an electric current for five hours, fifteen seconds each minute. At the end of five hours the shrinkage of the nuclei was found to be 48.8 per cent. It required fully twenty-four hours of rest for the cells and nuclei to resume their natural size and appearance. The fatigue caused the interstitial substance of the cell to disappear, as shown by vacuoles and lighter granulation, while the nucleus collapsed bodily.

Table I.—This showed that stimulation of two and one-half hours, intervals of rest and stimulation being two minutes each, produced a shrinkage of the nuclei of 24 per cent.

Table III.—Stimulation of three and one-half hours, five stimuli every second, one minute of stimulation alternating with one minute of rest, to sciatic ganglia of right side, caused a shrinkage of 36 per cent.

Table V.—Stimulation of seven hours' duration, at intervals of one minute, in a cat, caused an average shrinkage of 28.6 per cent.

To show how very carefully these observations were conducted, one hundred cells with their nuclei were measured, and their mean diameter ascertained. As a result of fatigue from electrical stimulation there was seen marked decrease in the size of the nucleus, with change from a smooth and rounded outline to a jagged and irregular outline; loss of open reticular appearance, with darker stain. The cell protoplasm showed slight shrinkage in size, vacuolation, and lessened power to stain. The cell capsule was decreased in size.

The processes of recovery were the reverse of the elimination. The protoplasm seemed to recover not infrequently slight[illegible] six and one-half hours little sult; an absorption too insig[illegible] seen. The nuclei, on eral icterus giving objective sig[illegible] not being entirely cause slight hemolysis of some red [illegible]ours.

That bile is a powerful hemolysin is w[illegible] sparrows nized. Slight resorption of bile would be am[illegible] destroy sufficient red cells to occasion an incre[illegible]

and swallows were also most carefully studied in the same article by Professor Hodge. The nerve cells of rested birds in the morning were compared with nerve cells of birds of the same size in the evening, after they had been flying about all day. The examinations of the specimens showed a great amount of change after a day's exercise. It exceeded that obtained by artificial stimulation. The greatest amount of shrinkage of nuclei, 69.7 per cent, was found in the occipital cortex of a female sparrow that had been working hard all day building her nest. (What could be more interesting?) The spinal ganglion cells of the same bird showed the next highest per centage of shrinkage, 64.5, as an index of the amount of fatigue. The recuperation from a night's rest must be very great, and in all probability made up this waste of nerve-cell tissue.

One of his experiments is so full of interest that I give it here in his own words: "On the morning of February 17 it began to rain, and continued nearly the whole day—a steady, warm, foggy spring rain. In the dense cover of the pine trees, over my window, the sparrows spent the day scolding and chattering at a great rate. None was observed flying about. At first I decided to abandon the experiment, thinking I should find little evidence of fatigue on such a day. On second thought, however, I decided to make a rainy-day experiment of it, and see what might result. I little expected the sharp and somewhat amusing result expressed in the table. Not an observable sign of fatigue was to be seen in the spinal ganglia, while traces of fatigue were slight in the cells of Purkinje (second layer of cells in the cerebellum). Perfectly clear, however, were the marks of fatigue in the nuclei of the cerebral cortex, as though while confined by the rain the little birds had kept up a deal of thinking."

In order to show how clearly and naturally this original investigator thinks and studies, I will here bring forward some of his own remarks about swallows: "Perhaps the most active bird that we have is the swallow. Quick, vigorous, powerful, careful in all its actions, it must require an enormous amount of nervous energy to coordinate its countless movements for a long summer day. There is nothing lazy or stupid about the swallow. When their work is done they play games and fly races, and with all the energy required for flying they still have enough left to do no end of talking, for their cheerful *zwitschern* is continually in my ears while I write. At one hundred miles an hour for ten hours—and I have observed them as early as five o'clock in the morning, and as late as eight in the evening—a swallow might cover a distance of one thousand miles in a single day. If a bullet of the same weight were to traverse the same distance at the same speed, an enormous explosion of energy would be required, and the living arrow can require no less."

"At five o'clock in the morning a large male swallow was shot, and within five minutes his brain and spinal ganglia were in their proper hardening fluids. A few minutes before eight in the evening another male swallow was taken down, and by eight his brain and spinal ganglia were treated like those of his brother in the morning. Signs of fatigue were everywhere present in the parts examined, but the brain gave the most agreeable sur-

prise. The cerebellum showed the highest per cent. of loss, nearly 10 per cent. more than the cerebral cortex. To the cerebellum is ascribed the work of coordination, and where could be sought an instance of more delicate manipulation than must be required to drive the wing of a swallow as it flits and whirls and balances and wheels and darts the whole day long?"

The brains of honey bees were also compared, and it was found that those that had been at work all day showed a shrinkage in their cells of from 19 to 75 per cent., as compared with the brains of similar bees in the morning. Great is the recuperation from fatigue of honey bees. The food they gather must be very nourishing and sustaining. More recent experiments by Professor Hodge, in which the brains of young animals suddenly killed showed the dendrites and contact granules uniformly expanded in rested neurons, while in fatigued ones the dendrites were contracted and varicose.

That celebrated poison, woorara, which the South American Indians use to poison their arrows with, when injected into the human system has long been known to cause paralysis of the terminal branches and peripheral plates of the motor nerves (peripheral neurons, we must now say), so that the nerve force no longer connects in such a way as to produce muscular contraction. This poison, according to the experiments of Hammond and Weir Mitchell, seems to act directly upon the heart, probably through the ganglia in its tissue, as well as upon the voluntary muscles. It also destroys the reflex functions of the spinal cord. Strychnine, on the other hand, is equally well known to increase the excitability of the nerve cells in the spinal cord, manifesting itself in muscular spasm when taken in poisonous doses. In the case of woorara it might be said that the protoplasmic processes of the nerve cells can no longer come in contact with the projections of other nerve cells; in the case of strychnine, that they are in too close contact, and cannot let go. It is not improbable that the action of all medicines, and the different effects of the same medicine when taken in small or large doses, may be partly explained in this way by their producing an ultimate chemico-mechanical effect on the nerve cells in different parts of the body. It is also supposable that the action of different poisons on the nervous system, whether the poisons are generated in the body itself or are introduced from the outside, may in great part be explained in this way. Thus, before long, we may have a new system of therapeutics based on a new system of neuropathology.

We have all felt the lassitude of extreme fatigue, which might now be explained by saying that it is due in great measure to shriveling of the nerve cells, preventing contact of their projections, and most of us, when young, have probably suffered from cramp in our calves after a hard day's tramp, which, according to this theory, would be due to the nerve-cell processes, the terminal arborizations and the dendrites having got too closely interlocked from the irritation of waste products, showing itself in muscular spasm. That we may have from retained waste products of excessive exertion both relaxation and cramps is not without its analogy in poison introduced into the system from without. Lead, for instance, causes paralysis and relaxation of the extensors of the hands, while in the abdomen it often induces spasms, cramps, and colic. From experiments in animals, Earnest Harneck[3] concluded that lead colic is due to intense excitation of the intestinal ganglia by the lead, producing arrest of peristalsis from spasm of the muscular coat. Shall we say that the neurons that preside over the nerves that move the extensors have their protoplasmic processes immovably retracted so that they can no longer vibrate and articulate, while those that control the intestines and abdominal walls are in too close connection, spasmodically interlocked, or ankylosed?* However this may be, strychnine is one of the remedies relied upon for the paralysis of lead after its elimination by other remedies, and perhaps it acts by bringing the neurons into better condition for normal contact. A new explanation may thus be afforded for the action of excitomotor remedies, such as strychnine, ergot, digitalis, etc., and also, though just the opposite, for depressomotors, such as the bromides, chloral, gelsemium, conium, etc. The action of other remedial agents, internal and external, might be explained more or less in the same way.

Tea and coffee are said to stimulate the ameboid movements of protoplasm. At times they certainly aid in stimulating thought and in forming new combinations of ideas, perhaps by bringing about different relationships of the cortical neurons. Tobacco, on the other hand, by its sedative and relaxing properties, seems to suit some students better in the collection of their thoughts, which, according to this theory, would be by causing relaxation of cortical neurons that had been too much preoccupied in loving embrace or close contact, and thus allowing others to form new combinations.

The effects of tonics, stimulants, and sedatives, whether of a chemical or mechanical, electrical, thermal or dynamical nature, upon central and peripheral neurons, are probably similar, simultaneous, and parallel to what they are upon voluntary and involuntary muscular fibers. Hence the state of the muscles is very likely a good barometer of what is going on at the other ends of the nerves that supply them in brain or spinal cord. Every muscle reader is a mind reader, and he who has the *tactus eruditus* well developed, be he a physician or a masseur, has an immense advantage in the diagnosis and treatment of neuromuscular troubles. Every horse is a mind reader by the tension of the reins. In two cases of hemiplegia recently under my observation there was much spasm (contracture) of the flexors of the hand and arm. The patients were both receiving the faradic current, which is well known to stimulate muscular contraction, and were taking strychnine internally. As soon as the faradism was stopped the spasm became less; and later, when the strychnine was left off, there was still greater improvement; the contracture almost entirely disappeared, allowing the opposing paralyzed

*Sir T. Lauder Brunton tells us that one of the most painful experiences of his life was that of being nearly tickled to death by a nurse when he was a small boy. He can never forget the agony of it. This leads him to believe the statement that Simon de Montfort, during the persecution of the Albigenses, put some of them to death by tickling the soles of their feet with a feather. The neurons may have become so tightly interlocked that they could not let go. Perhaps something of the same kind occurs in tetanus.

extensors to come into play as much as they could. In these cases the effects of the strychnine and faradism might have been, and probably were, simultaneous upon central and peripheral neurons, terminal arborizations, and muscular fibers.

The effect of stimulation upon protoplasm is, when sufficiently strong, to cause an immediate cessation of movements and withdrawal of protruded processes into the main substance.*

Upon cessation of the stimulation, if it has not been too strong, the movements will begin again; but if so severe as to injure the living substance, they stop forever. Mechanical stimuli and abrupt changes of temperature act in like manner. It is quite conceivable that nerve cells and their projections behave in the same way.

Recent experimental studies tend to strengthen the theory that neurons act by contiguity and not by continuity. Lutzenberger studied the changes in the nervous systems of guinea-pigs, after slight injury to the head and spinal column, and found that the general disorders of nutrition showed themselves most prominently in the increase of the number of ganglion cells that presented all styles of retrogression.[4]

Parascondola has also made an extensive study of the effects of shock upon guinea-pigs. He stretched them out flat and gave them a sharp blow upon the abdomen with a flat ruler. The animals reacted in various ways. Most of them, after a period of quiet, seemed to recover, but in from thirty-six to forty-eight hours they died with symptoms of exhaustion or shock. The cerebrum, cerebellum, medulla, and spinal cord were removed for microscopic examination. The alterations found were deformities of the cell bodies to the extent of actual atrophy, nodelike swellings on the dendrites, and fragmentation of the same. There was also found degeneration of the posterior roots, proceeding even to degeneration of the posterior columns. Changes in the cellular protoplasm were also seen—rarefaction proceeding to vacuolation in the nucleus, and vesicular swelling of the nuclear protoplasm.[5]

These were very serious alterations, and all tend to throw light upon the nature of fatigue, shock, neurasthenia, and hysteria arising from injury. But percussion, though harmful in large doses, is often beneficial in small ones, stimulating languid nerves and muscles, and sometimes relieving painful ones by overinciting them and wearing out their irritability, and presumably at the same time favorably influencing the vibrations and connections of nerve terminals and dendritic processes.

It seems rather curious that those who have furnished the clearest objective evidence that nerve cells and their projections act upon each other by contiguity and not by continuity, are not the ones that have advanced this theory at all. Thus Professor Hodge, in the *Journal of Morphology* for 1892, the MEDICAL RECORD, March 26, 1898, and in previous publications, says nothing of this theory, and yet he has furnished the clearest objective evidence of it. Credit is given to two Frenchmen, one M. Lepine, for having first advanced this theory in the *Revue de Médecine* in 1894; and the other, M. Mathias Duval, for agreeing with him in the *Comptes Rendus de la Société de Biologie*, 1895. These gentlemen must have had exceedingly brilliant imaginations, for they scarcely ever refer to the labor of others, and not at all to those of Professor Hodge, that would have furnished them with objective evidence confirmatory of their theory. This seems to be always a rapid way of becoming famous. Their hypothesis seems to have been evolved from a single case of hysteria of a peculiar kind that suddenly passed from complete deafness to acute hearing, and which they explained by saying "that the anesthesias, sensitive and sensorial, and the motor paralysis in the hysterical, are due to imperfect contact between the ramifications of the nerve cells"; and the disappearance of these morbid states is owing "to an erethism of the prolongations of the nerve cells, by which they are brought into normal contact, attention sufficing to reestablish the contacts."

When distinguished gentlemen like these are allowed to hold this theory on such insufficient evidence and with so little regard to the testimony of others, it behooves us to ask if this theory or something like it has not been promulgated before, for it has given these men great renown, and neurologists are disposed to believe in it. William H. Munroe of Boston was a very intelligent layman who had studied anatomy and physiology to a moderate extent. He died in 1887, at the age of eighty years. For the last thirty years of his life he was firmly and enthusiastically of the opinion that somehow or other in disease the nerves did not connect properly, and "to remedy this evil" (as he used to say) and to make them connect he relied on manipulation by hand, a mode of treatment in which he became very skilful, and which, viewed from recent light, he not altogether inappropriately called the "nervous-adjustment cure." He had a large clientele of intelligent people, most of whom were fascinated with his theory, while physicians smiled incredulously at the theory and the seeming irregularity of the practice. An association with him for three years before and while I studied medicine, from 1867 to 1870, convinced me of the efficacy of this treatment in the disturbances of nerves, muscles, and joints, mostly of a chronic nature. From observations of massage in this country and abroad, extending over thirty years, I may, perhaps, be allowed to say that he certainly had the best method of this art that I have yet met with. Wherever there was undue tension of the tissues, there the nerves were supposed to fail in properly connecting, and the thorough, agreeable, and efficacious manipulation of the offending region often proved beneficial; and even when it failed to do good it left behind it a pleasant impression, far different from that after the scraping, greasing, and slapping that too often passes for massage. Indeed, the word massage is becoming subject to so much abuse that perhaps such an expression as manipulation or manual treatment had better be adopted in place of it, for more depends on the skill

*Several years ago I was knocked down by a "scorcher" on a bicycle, taken home in an ambulance, and had my scalp sewed up. Not only was I unconscious for three hours after the accident—amnesia—but also had complete forgetfulness of events for fifteen minutes before it—retroactive amnesia. Next day I was out as if nothing had happened, and thirty-six hours after the accident I was back at my office as well as usual. But I do not care to be the object of experiment of any more disconnection of neurons.

and experience of the manipulator and his understanding of the disorders than in the use of any "highfalutin" words to cover ordinary rubbing.

An excellent example of the disconnection of neurons and their subsequent re-connection is given by Dr. G. F. Boehme, Jr., in the MEDICAL RECORD of Aug. 3, 1918, p. 183: A lady of an hysterical temperament who had two sons in the army went to an amusement park and was startled by the explosion of fireworks. She gave a brief cry and became deaf. Examination revealed no aural defect. She had a definite corneal and pharyngeal anesthesia. After being quiet for a few days she gradually recovered her hearing. She might have been cured by another explosion, or perhaps made worse, who can tell?

From the days of Hippocrates history affords parallel examples of theories formed in advance of their proof. For our present purpose we will cite but one, that of Asclepiades (128-56 B. C.), a Greek physician, who founded a school and practised at Rome, and was very popular with the Romans on account of his simple and agreeable remedies. He thought that physicians ought to cure their patients safely, quickly, and pleasantly, and with this object in view he relied mainly on diet, bathing, exercise, and friction. He considered that the body had innumerable sensitive canals running through it, in which moved the nutritive juices and plastic atoms. So long as this movement went on without disturbance health continued. But disturbance caused sickness, and the normal movement of these juices would be disturbed by abnormal increase of their atoms, by their irregular distribution, by too great blending together, and by too swift movement of the same, and also by dilatation and constriction of their canals. Proceeding on these principles, or theories, rather, Asclepiades renounced almost entirely the use of medicines and attempted to restore free movement of the nutritive fluids and plastic atoms by means of rubbing. The soporific effects of gentle stroking he also recognized. With friction he combined active and passive motion, and no doubt he was an adept at massage in his day. He thus foreshadowed the discoveries made long after of the functions of the vasomotor nerves and of the muscular coat of the blood-vessels in regulating the caliber of these vessels; and to a large extent, also, he predicted the pathology of inflammation in the congregating of white blood-corpuscles.

Seen from the light of recent studies of the neuron, the experiments of Professor Golz of Strassburg possesses new interest.[6] After opening the abdomens of animals and applying percussion by light and frequent blows over the stomach and intestines, the peritoneum at first became paler from constriction of the vessels, but continuance of the percussion caused dilatation. When the percussion was first applied over the abdominal walls, and these opened afterward, it was seen that the vessels of the abdominal cavity, especially the veins, were dilated and distended with blood. The heart's action was considerably retarded, owing to the reflex influence of the percussion upon the inhibitory action of the vagus, and also to the sudden withdrawal of blood into the vessels of the abdomen. Continued still longer, the pulsations of the heart became less, and finally ceased, as did also respiration.

Here we see the primary effects of percussion (a form of massage) causing constriction of blood-vessels from stimulation of their vasomotor nerves and muscular coat. Longer continued, this same percussion produces an opposite effect, dilatation of vessels from over-inciting them and wearing out their irritability, and with still more of it pulse and respiration cease. Corresponding to the first influence of percussion, we would now suppose that the projections of the neurons had been brought into closer juxtaposition; to the second, that they had got somewhat tired out and relaxed; to the third, that they had lost their capability forever to connect, and the animal dies. It would be exceedingly interesting to examine the neurons connected with the solar plexus of prizefighters when they knock the wind out of each other by a blow upon the epigastrium.

If this theory of the mechanical action of nerve-cells and their processes holds, then remedial mechanical measures, such as massage, kneading, stroking, percussion, passive and resistive movements, all of which act upon peripheral and central neurons, will receive an additional explanation to what we already know of their effects upon skin and muscles, blood-vessels, lymphatics, and nerves. We would then say of a nervous person with too much tension, who cannot let himself go to rest, that under the influence of appropriate manipulation he is soothed and quieted to sleep; that his peripheral and central neurons have been coaxed to relax; while on the other hand, if such a patient should receive too vigorous manipulations, the peripheral irritation caused thereby would induce both voluntary and involuntary resistance, increase the tension, and bring the processes of the neurons into still closer contact. Or take languid individuals with flabby tissues and give them pretty vigorous manipulation. Their muscles tone up and become firmer; then we will have to presume that their neurons have come into closer and more natural contact. It was old Hippocrates who said in his aphorisms that "Hard rubbing binds; soft rubbing loosens; much rubbing causes parts to waste; moderate rubbing makes them grow."

By means of training and repeated efforts paths of resistance in brain, spinal cord, and nerves are made easier; thought, will, and action become less difficult, and the terminal arborizations of the neuraxons and their collaterals connect more readily with the dendrites of the nerve-cells, constituting what is usually called education, which should be so adjusted

> "That outer man and inner soul
> Maintain their balance true,
> Till every string on being's lyre
> Gives forth its music due."

On the whole, this theory that nerve-cells and their processes act upon each other by contiguity and not by continuity would seem to be consistent with the behavior of other tissues, and even with the propagation, prolongation, and cessation of life itself.

520 BOYLSTON STREET.

VALUE OF THE WASSERMANN REACTION.*

By ROBERT A. LAMBERT, M.D., MIRIAM P. OLMSTEAD, AND HAROLD C. STUART, M.D.,

NEW YORK.

RESPECTIVELY VISITING PATHOLOGIST, RESIDENT BACTERIOLOGIST, AND ASSISTANT RESIDENT PATHOLOGIST, PRESBYTERIAN HOSPITAL.

In the twelve years which have elapsed since the method of complement fixation was applied by Wassermann to the diagnosis of syphilis, an enormous amount of clinical and serological data has been collected and published bearing upon the question of the specificity of the test. It was early recognized that the reaction was not, strictly speaking, a specific one, in that in carrying out the test it was not necessary to use as antigen either the syphilitic virus or any essential derivative of it. Nevertheless, reports from numerous observers soon brought general acceptance of the view that a positive reaction was obtained in a high percentage of cases of clinical syphilis, and that among non-luetic cases a negative reaction was the rule.

While more recent reports have in general served to confirm or even broaden the earlier claims as to the value of the test, increasing emphasis has been placed by serologists on the delicacy of the reaction and the possibility of variations in results from relatively slight modifications in technique. It has been recognized, too, that certain conditions, such as acute infections associated with high fever, may give rise to positive reactions in non-luetic cases.

Very conservative, or even sceptical, views regarding the practical value of the test have not been lacking. Here and there reports have appeared in which it has been maintained that not only is the reaction negative in a large percentage of cases of syphilis, but also that positive reactions are so often reported in cases in which there is no clinical evidence of syphilis, that the test may be very misleading, if considered alone. An article embodying essentially this view, by Symmers and his co-workers at Bellevue Hospital, appeared recently in the *Jour. Amer. Med. Assn.*, 1918, LXX, 279. Since we shall have occasion later to refer to the results obtained by these authors, it may be well to quote their conclusions:

"1. Depending on the antigen employed, the Wassermann reaction in the living patient, as carried out at Bellevue Hospital, gives a negative result in from 31 to 56 per cent. of cases in which the characteristic anatomic signs are demonstrable at necropsy.

"2. The Wassermann reaction in the living patient is positive in at least 30 per cent. of cases in which it is not possible to demonstrate any of the anatomic lesions of syphilis at necropsy."

The Wassermann test is being widely used, and, as Symmers and his assistants point out, much reliance is being placed on it by Boards of Health, hospitals, practitioners, and the public. The question of the reliability of the test is therefore one of very great importance. If the results obtained at Bellevue Hospital, which show so large an error in both directions—that is, in the high percentage of negative reaction in syphilis and in the demonstration of many positive reactions in non-syphilitic cases—have a general application, then the wide use of the Wassermann test is not only of doubtful benefit, but even a source of much harm, unless this wide margin of error be clearly recognized.

The importance of this question led us to make a comparative study of the serological and autopsy findings at the Presbyterian Hospital, similar to that made by Symmers and his coworkers at Bellevue Hospital.

The Wassermann test has been used in the Presbyterian Hospital some six or seven years, but it is only in the past three years that a uniform technique has been consistently followed, and of which the details can be presented. During the preceding years the serological work was done by several laboratory workers; and since we have no record of the details of the technique followed, except as to the antigen employed, we have thought it advisable to present and discuss only the data compiled in this last three-year period.

The autopsies during this period were performed by or under the immediate direction of Professor W. G. MacCallum, Dr. A. M. Pappenheimer, and Dr. R. A. Lambert of the College of Physicians and Surgeons. Complete autopsy protocols were recorded in every case, including gross and miscroscopic description of all organs—with the exception of the central nervous system in a certain percentage of the cases. In every instance, microscopic sections were preserved, and have been studied again in the preparation of this report. It has been possible, also, to reexamine many of the gross specimens, which had been preserved in the museum for teaching purposes. In this review of the pathological material, however, a change in diagnosis was made in only three instances. Two cases showing microscopically definite syphilitic aortitis had been overlooked and the syphilitic nature of a scarred liver had, in one instance, not been recognized. It should be clearly stated that only those cases which showed definite syphilitic lesions were placed in the group of positive anatomical syphilis. Those showing suspicious, but not clear cut luetic lesions—a relatively small number of cases—were placed in the doubtful group.

Since differences in results obtained with the Wassermann tests are undoubtedly due in large part to differences in technique, we shall give in some detail the method in use at the Presbyterian Hospital.

Two antigens are used in all tests: a crude alcoholic extract of guinea pig heart and a cholesterinized extract of guinea pig heart. The ice-box fixation method for four hours is employed with the alcoholic antigen; water bath fixation at 37 deg. C. for ½ hour with the cholesterinized antigen. Serum is inactivated ½ hour at 55 deg. C. The sheep system is used. Complement for each guinea pig is titrated separately, against 1½ units of amboceptor, and is so diluted that a dose of 1½ units is used in the alcoholic tests, a dose of two units in the cholesterin tests. Each specimen of complement is also tested with varying amounts of the cholesterin antigen, the amount to be used in the tests, twice, three times, and four times that amount. Any specimen that fails to hemolize completely in the presence of the cholesterin antigen

*A correlation of the seriological and post-mortem findings at the Presbyterian Hospital, New York.

is not used in the cholesterin tests, but it may be used with the alcoholic antigen, if its hemolizing power is good, according to the complement titration. An amboceptor titration is made with each mixture of complement; that for the alcoholic tests and that for the cholesterin, and for sensitizing the cells, the amboceptor is so diluted that one dose contains 2½ units. Tests are read as soon as hemolysis is complete in the antigen and serum controls, in which there is double the amount of antigen and serum used in the tests. By a ++++ reaction is meant complete inhibition of hemolysis in 0.2 c.c. of serum. Degrees of incomplete inhibition are indicated roughly by +++, ++ and +. Only a ++++ reaction is considered positive.

Table I.

Autopsy Findings.	No. Cases.	Wassermann	Wassermann	Wassermann	
		++++ Both antigens	0 Both antigens	+, ++, or +++ with either antigen	
Positive	23	18	3	2 (trtd.)	= 85.7 per cent positive (excluding 2 treated cases giving doubtful reactions).
Negative.....	188	0	175	13	
Doubtful...	3	2	0	1	
Total....	214	20	178	16	

The results of the comparison of the serological and autopsy findings can be best presented in the form of tables. On the basis of the post-mortem findings, the cases are divided into three groups: (1) syphilitic or "positive" cases, (2) non-syphilitic or "negative" cases, and (3) doubtful cases. Table I shows at a glance the results of the Wassermann test in these three groups.

It is seen that of 23 cases showing definite syphilitic lesions, 18 gave ++++ Wassermanns (both antigens), 2 (treated cases) gave doubtful reactions with one or both antigens, and 3 gave negative reactions. That is, in 18 out of 21, or 85.7 per cent. of cases of proven, *untreated* syphilis, a ++++ Wassermann was obtained during life. It will be recognized that this percentage of positive Wassermanns is relatively high, when consideration is taken of the fact that most of the cases were examples of late syphilis, as indicated in Table IV. There were three cases in which the autopsy findings were not conclusive, and which are classed as doubtful syphilis. One was an example of a coarsely nodular cirrhosis of the liver associated with a chronic interstitial orchitis and chronic meningitis of possible leutic nature. The second was a case of nodular cirrhosis of the liver with an inflammatory reaction which suggested lues. In the third case, death was due to lobar pneumonia, but chronic interstitial orchitis was found, which suggested a possible old, leutic infection. The last two cases gave a ++++ Wassermann reaction, the first a doubtful reaction.

The most striking fact, in our opinion, brought out in the table, is, that of 188 *cases showing no evidence whatever of syphilis at autopsy, not one had given a ++++ Wassermann during life.*

In Table II the data are so arranged as to bring out the significance of the Wassermann in the light of post mortem findings. In other words, the figures constitute the pathologist's answer to the question as to what a positive, negative or doubtful Wassermann reaction means. The table shows that 20 cases gave a ++++ Wassermann with both antigens, and that, in 18 of these, definite evidence of syphilis was found at autopsy. One of the two remaining cases showed suspicious lesions in the liver, very probably syphilitic, and the other a chronic orchitis, possibly syphilitic, but since this second case was one of pneumonia and was bled while running a high temperature, the ++++ Wassermann may be regarded as non-specific. It is seen, therefore, that 18 out of 20, or 90 per cent. of positive Wassermann reactions were conclusively confirmed by autopsy findings, and that in the two remaining cases suspiciously syphilitic lesions were present—a possible margin of error of 10 per cent. Of 178 patients giving negative Wassermann reactions with both antigens, only 3 showed definite syphilitic lesions at autopsy. Hence, the negative Wassermanns were confirmed at autopsy in approximately 98 per cent. of the cases, a margin of error less than 2 per cent.

Table II.

Wassermann.	No. Cases.	Autopsy Findings		
		Pos.	Neg.	Doubtful.
++++ (both antigens).	20	18	0	2
0 (both antigens).	178	3	175	0
+, ++, +++ (with either antigen)	16	2*	13	1
Total	214	23	188	3

*Treated cases.

Sixteen patients had given a doubtful (+, ++, or +++) reaction with one or both antigens. Two were cases of definite syphilitic aortitis which were being treated. One case showed suspicious lesions in the meninges, liver, and testes at autopsy. In the 13 remaining cases, no anatomical evidence of syphilis was found. Excluding the two doubtful reactions in the cases under treatment, 13 out of 14, or 93 per cent., approximately, of the doubtful Wassermann reactions were non-specific as judged by autopsy findings. It is a fact worthy of note, that 11 out of 16, or 69 per cent., of these doubtful reactions were given by the cholesterin antigen only. Four specimens gave a doubtful reaction with both antigens,—one a treated case of syphilis, and one a case of possible syphilis. In only one instance (a case of sarcoma of the ovary) was there a doubtful reaction with the alcoholic antigen alone. It is thus evident, that while the cholesterin antigen may have the advantage of giving more reactions in cases of syphilis, and of more nearly excluding syphilis, it has the disadvantage of giving a considerably larger number of apparently non-specific reactions, as judged by autopsy findings.

Discussion.—The data presented above show a very close parallel between the serological and autopsy findings at the Presbyterian Hospital during the past three years. Though the number of cases is somewhat smaller, the character of the material is very much the same as that which forms the basis of the report from Bellevue Hospital by

Symmers and others quoted above, in which very different conclusions were reached. At Bellevue Hospital, a positive Wassermann was obtained in only 44 to 69 per cent. of the cases of syphilis demonstrated at autopsy, as compared with 85.7 per cent. at the Presbyterian Hospital. Furthermore, the authors report positive reactions in 30 per cent. or more of the non-syphilitic cases, whereas we failed to find among such cases a single ++++ Wassermann, and only 7 per cent of doubtful (+, ++, +++) reactions.

Miscellaneous	5	5		
Total.	23	18	3	2

The question naturally arises as to the reason for the difference in results at the two institutions.

The nature of the data, both pathological and serological, which forms the basis of reports of this kind, is such that a fair critical review is not possible except upon a close examination of the material itself, with careful regard to the details of the methods used.

We shall therefore make no attempt to analyze the factors responsible for the differences between our results and those quoted, except for brief reference to one point:

At Bellevue Hospital the cholesterin fortified antigen was used alone in a majority of the cases. In 49 listed cases, in which both alcoholic and cholesterin antigens were used, the results with the two antigens differed in approximately 60 per cent. In our series of cases at the Presbyterian Hospital the two antigens were used in every test with only 6 per cent. of discordant results.

Conclusions.—A comparison of the serological and autopsy findings at the Presbyterian Hospital during the past three years brings out the following facts:

(1) Among cases showing anatomical evidence of syphilis at autopsy 85.7 per cent. had given during life a ++++ Wassermann with both alcoholic and cholesterinized antigens.

(2) Among 188 cases showing at autopsy no anatomical evidence of syphilis, 93 per cent. had given during life a negative Wassermann with both antigens and 7 per cent. doubtful reactions (+, ++ or +++ with either antigen).

These findings, in our opinion, warrant the conclusion that the Wassermann test, properly carried out, can be relied upon as an important aid in the diagnosis of syphilis.

GASTROINTESTINAL HEADACHES.

BY J. RUSSELL VERBRYCKE, JR., M.D., F.A.C.P.,
WASHINGTON, D. C.

OF the many causes of headache, disturbances of the digestive apparatus account for many, probably equally as many as eye troubles. The largest number are from absorption from the bowel. These headaches may be of severe migrainous character, often dull frontal, less frequently occipital, and rarely neuralgic. They may come in attacks with perfect freedom in the interval or the head may never feel just right. There are found very frequently, in combination with the pain, various other nervous derangements, such as dizziness, easy fatigue, sleeplessness or the opposite, and many other symptoms.

A few in whom headaches are traceable to the gastrointestinal tract show hyperacidity or gastric stasis as the cause. One of the most spectacular cures on my records belongs to this class.

Mr. W. P. J., a clergyman, age 30, was referred to me Feb. 27, 1912, by Dr. Kearney. He had had no illness during his life, excepting typhoid fever many years before, but suffered from attacks of severe prostrating headaches for which he had to take paregoric. He would be very apt to spend every Monday flat in bed. He had worn glasses for 10 years but the ache was clearly not from his eyes. Examination was entirely negative with the exception of his gastric contents. There was some food retention of fat and some excess of acid, free HCl being 50 and total acidity 70. He was given general directions as to living and put on a fat free diet for a short time, and had a few stomach washes, with the result that he had no further headaches for some weeks when he partook rather liberally of fat ham. This caused him to have a headache, but two more stomach washes were sufficient to make a permanent cure. He later told me that he felt as if he had 50 extra working days a year added to his life.

This case is, of course, an exception in the speedy and complete relief after headaches of such severity and such a long period of time, but my records show many others hardly less remarkable in their response to treatment. One woman with basal headache caused by hyperacidity made but one call subsequent to receiving her list of directions, and sent a report some time later it had been unnecessary to return. Some of the gastric cases come for a stomach wash when the headache starts. They have learned the association of headache with gastric upset in their own cases. But a comparatively small number of gastrointestinal headaches fall within this group, however. One would imagine that many migraine attacks might be stopped by lavage, since bad attacks nearly always end with vomiting, after which the pain is relieved. This is not the case, however, in the majority of patients, as the vomiting is central in character, coming as the final explosion of nerve force before the attack subsides. So that artificially emptying the stomach does not usually serve to end the attack in most cases of true migraine.

By far the greater number of headaches of digestive origin are due to intestinal putrefaction and

absorption from the bowel. These patients almost always show marked indicanuria, sometimes constantly, again only preceding and during an attack. However, occasionally patients present themselves with headache and other more manifest symptoms of intestinal absorption in whom repeated examinations fail to reveal any indican. Some of these may have fermentation instead of putrefaction, but we have no test to differentiate intoxication, if there be any, from fermentation.

Some of the most marked obstinate cases of intestinal headache result from incompetent ileocecal valve with regurgitation of cecal contents back into the ileum. Such a condition is only demonstrable by means of the Roentgen ray, although it may be suspected in cases of marked intoxication in which an enema is not expelled at once but perhaps many hours after being administered and in which the enema often causes an accentuation instead of amelioration of symptoms.

We next come to the consideration of the cases in which the digestive tract is not the sole cause of headache, but in which it is an important contributing factor. In migraine, for instance, it may happen that any one of a number of factors may be sufficient to bring on an attack in the same individual. The following case will illustrate:

Mrs. C. M. E. age 42, was referred to me by Dr. Kelly in June, 1914, with a history of migrainous attacks for the past 15 years. They had at first been several months apart, but of late the intervals had been only 4 days to a week and she would vomit for 48 hours afterward at times. She was found to have gastrointestinal catarrh, slight putrefactive absorption, and mild hyperthyroidism. After her diet was regulated and general directions for living given her she went for 40 days before the next attack; in other words missing perhaps about 8 attacks, as they were running previously. I studied her case carefully and came to the conclusion that her attacks came through the thyroid but were precipitated by any one of four factors. First, she had lost her only daughter several years before. She was still mourning and went nowhere for recreation. On various days, such as her child's birthday, Christmas, and many other dates that had a special significance with her, she was bound to have an attack. Secondly, overwork would induce an attack as one would be pretty apt to follow the days that the maid did not show up and she did her own housework. Thirdly, an attack would come at the time of each period. The fourth factor was her digestion. This was the first to be remedied with the elimination of a great many headaches. Her grief was in a measure controlled after a hard fight so that this factor was removed. The influence of menstruation was the one thing which could not be helped, so that she continued to have one headache a month, but there was a wonderful diminution in the frequency. The inability to do away with the migraine at the menstrual period in this case is in the line with my experience in all these patients, and I will speak of this phase later.

Ocular disturbance and digestive disorders are frequently associated in the production of headache and the correction of vision is not enough in itself. In fact, it is often impossible, since the lens required will often vary from week to week until the effect of toxemia is removed. I have had quite a number of patients referred to me by ophthalmologists with the statement that eye trouble was present, but that it seemed impossible to find a suitable lens for the patient. It is best therefore to correct toxemia before the eye examination if the price of frequent changes of glasses is of any moment.

Mr. F. G. D. consulted me in May, 1917, with the complaint of basal headache, dizziness, nervousness, and weakness. He had worn glasses for several years and they had been changed several times. He was about to go again for another examination. I found that he had intestinal putrefaction with indicanuria, which probably influenced the eyes and head. He was told to give Dr. Burke my report on the toxemia as it might influence the examination. Dr. Burke reported that he considered the eye disturbance to be the result rather than the cause in this instance and after the indican disappeared his former glasses suited him perfectly and the headache disappeared.

Mr. T. S. R. was referred to me by Dr. Henning. He had had headaches all his life, maybe once a week, through the eye and temple. At times there would also be lassitude and easy fatigue. He had been examined by numbers of oculists. He was found to have vagotonia, a slight degree of chronic appendicitis, and some hyperchlorhydria. Belladonna and alkalies, with attention to the diet and a few enemas, served to make a new man of him in a short time.

I have already mentioned one case of deranged internal secretions in association with digestive disturbance as the cause of headache. We know very little of the ductless gland disorders, but we know that headaches can occur, and further we know that nearly all disturbance of the glands of internal secretion is preceded by either infection or toxemia, so that it is not too much to assume that intestinal toxemia can play a not inconsiderable part in the causation of this class of case.

I know little of aural headaches, but I have had several patients with headache and dizziness suggestive of labyrinthine disease in which the real cause was intestinal. So also in the class of patients with migraine dependent on swelling of the mucosa of the turbinates, I believe intestinal absorption and protein sensitization can play a part, but this is only theoretical, based upon the swellings of different mucous membranes which may occur from the action of foreign protein. I have no cases to bear me out.

The one great class of cases of headache which appears to me to be beyond hope of cure embraces those occurring at the menstrual period. Digestive headaches which may be present in the interval may be cured, but the regular monthly attack persists. I have never seen these monthly headaches of the migraine type cured before the menopause. So, when I give my prognosis as to the cure of headache I always except these.

From what has been said above it might be thought that I consider that the stomach and intestines play a part in the etiology of all headaches. This is certainly not so, and I have simply mentioned their possible association with trouble in the other organs in order to emphasize the point that the digestive apparatus should at least always be considered in the treatment of the headache patient, even if actual trouble has been found elsewhere.

Returning to the subject of pure gastrointestinal headache unassociated with disease of other organs, we arrive at the question, How can we tell whether the headache comes from the digestive tract or not? I do not think that we can. The patients will often say that they think their trouble comes from the stomach. The only thing to do, however, is to make an absolutely complete physical examination, with tests of the gastric secretion, of the urine for indican, etc. If indican is present in considerable amount it is probable that intestinal putrefaction

is the principal cause. It can only be said that such and such a finding is not normal and is sufficient to cause the trouble. Whether it does so can be found out only by correction of the thing found wrong.

The prognosis in the uncomplicated cases is good. I think a man has a better chance for complete cure than a woman because of the possible influence of the pelvic organs. If the cause can be found and eradicated the results are often marvelous and the whole life of the patient is made more worth while. I often think that if I have made mistakes in the practice of medicine and have had failures that the relief which has come to a few patients after years of suffering has made up for the defeats. And sometimes relief comes so quickly and easily.

Mr. B. H. I was able to see only once for the examination, as he came from Fredericsburg. The rest of his treatment was conducted by mail. For years he had left-sided migraine in attacks lasting 12 to 18 hours, coming about once a week. But between attacks he was never quite right as his head had a heavy clouded feeling and he was almost incapacitated for work. While he was a civil engineer he had taken to farming for his health but still suffered. He was found to have spastic colitis with ileocecal regurgitation. I last heard from him 7 months after his tratment and he reported that since his treatment he had been knocked out only twice in the 7 months with a few mild headaches in between. What a difference this is from approximately the 30 prostrating attacks he would have formerly had during this time.

Mr. W. L., referred to me by Dr. Walker, is still under treatment although reporting at rather long intervals. He was hardly ever without headaches of the dull sort, easy fatigue, and lack of energy. This had been as far back as he could remember of his 52 years. He also while a city man had taken to farming. He was found to have indicanuria, as an index of autointoxication and colonospasm. Since the day of beginning treatment he has had no bad headache. He still has somewhat of the intoxication left and his head does not always feel clear, but he remarked that if he never improved any further he would be satisfied.

All cases are not like these by any means, but think of the wasted and painful years for want of a simple test and short treatment! We do not cure all of the headaches, nor do we even help some of them, yet we can cure all that come from intestinal absorption, and these cases, more brilliant than others, have been selected to show what can be accomplished and to emphasize the importance of looking for indican as a routine part of every uranalysis. I regret to say it, but there are some men practising medicine who do not even know what indican is and what it stands for.

In regard to the treatment of these cases there is no specific. Each wrong must be corrected. Hyperacid stomach must be neutralized. Vagotonic conditions call for belladonna. The diet must be selected for the different conditions found, but a rather low protein intake is usually indicated.

The cases of absorption from the bowel are the most interesting to me. They call for attack along three distinct lines. The poisons must be eliminated. The production of the poisons must be limited by the intake of less of the particular material which is capable of being broken up by the putrefactive bacteria, and by the attempt to change the intestinal flora or to kill many of the bacteria by antisepsis or biological means, which will be considered in a minute; and lastly conditions favoring absorption of toxins already produced must be corrected as by the healing of colonic ulceration and the attempt to get an imperfectly working ileocecal valve to functionate perfectly.

We will consider these methods of treatment seratim. The poisons produced must be eliminated, and this must be done, not with laxatives or cathartics, but mechanically by washing. Patients are often made much worse by calomel and other physics. The reason for this is easy to understand. The toxins are generated in the lower bowel by bacteria putrefying bits of undigested protein. When a laxative is given, it does, to be sure, eliminate the toxins already in the colon, but it also quickens peristalsis all along the tract so that a much larger amount of material is brought to the colon from the small intestines to supply extra ammunition for the bacteria. Bowel washes are always necessary. They may be in the form of medicated enemata or irrigations in most cases. These also serve the purpose of helping in the healing of a diseased mucosa. To be successful they must be administered correctly and the patient is not always successful in taking his own treatment. It is safer for the physician or nurse to give the treatments.

In case an enema is not well taken, if there is difficulty in expelling it, and in all cases of incompetent ileocecal valve, washing from above through the duodenal tube is indicated instead. It is possible to introduce a tube into the duodenum with no discomfort in several minutes. Then when a quart of solution is rapidly put into the duodenum it is swept along, carrying everything with it and is expelled in from 8 minutes to a half hour usually, thereby cleaning the entire tract without the loss of body fluid such as would result in case of salines administered.

The diet should be limited in protein, particularly the sorts of protein which are less completely digested. Meat particularly should be entirely eliminated or much reduced. No patient eats meat without some bits showing in the stool microscopically. A few million bacteria can make quite a meal from a microscopic meat fiber. It has been attempted by the feeding of large quantities of carbohydrates to change the intestinal flora to another type. I must admit that my results have not been very successful.

The bacteria of the putrefactive type must be to a certain extent gotten rid of by some means, however, and we have here our choice between biological and chemical methods. Bulgarian bacilli have been greatly lauded not only by the manufacturers but by many physicians. My experience with the class as a whole has not been favorable nor with certain exceptions has it been constant. In children I find the Bulgarian bacilli to be much more efficacious than in adults. Further, I find my results to vary with the manufacturer. From two preparations I believe I have had some good results after some other things had failed. But on the other hand I have seen each preparation fail and something else succeed. I continue to employ them in some cases even though not sure of their actual value. A preparation containing petroleum jelly I use when there is need for a lubricant.

A new form of biological therapy is that of cultures of the *Bacillus acidophilus*. I have only recently become interested in this preparation and

can not testify as to its value. I can say so far, however, that I have had several cases of indicanuria which had persisted in spite of all other treatment clear up shortly after starting the administration of these bacilli. It is claimed that they will actually colonize in the bowel while the Bulgarian bacilli will not.

When we come to the question of chemical extermination of the bacteria most physicians will say, "It can't be done." I believe that we can come closer to it now than we ever could before. I have used extensively a phenol derivative for which there has been claimed nontoxicity as it is non-absorbable, but with a carbolic coefficient of 40, endeavoring to satisfy myself as to its value. I am on the fence. I will admit that it is probably the best thing in the way of an intestinal antiseptic we have ever had, but it will not always stop intestinal putrefaction as controlled by the symptoms and the indican test. It is often possible to completely deodorize the stool by the administration, but I am unable to explain why some cases which have resisted local treatment and Bulgarian or acidophilus bacilli will immediately clear up under the same treatment with the substitution of the antiseptic for the bacilli, while other patients uncured when treatment is begun with the antiseptic get well when the bacilli are given.

I can say, therefore, that one after the other of these means should be tried, and to date I hardly know, after the treatment of several hundreds of cases of autointoxication, the relative value of each in an individual case. But the main thing I wish to bring out in considering the subject of these cases is the importance of regarding the digestive tract as the cause or one of the causes. Then by persistence, and the trial of one of the methods after another if necessary, a cure can often be accomplished.

THE ROCHAMBEAU.

RETROPHARYNGEAL ABSCESS IN INFANTS.

BY A. NOAH SCHILLER, M.D.,

NEW YORK

ALTHOUGH first described by Bokai many years ago, the condition called retropharyngeal abscess, whose occurrence is more frequent than one is apt to suspect, has not had the proper amount of investigation and study. As Henoch says, it is as good as unknown to most physicians. The fault lies with the practitioner of medicine, because the diagnosis does not demand any great amount of skill, but only a more complete examination of the patient.

The examination of infants is never complete unless there has been a thorough inspection of the pharynx. This at times is difficult. Then the sensation of touch must be brought into use. The finger should be inserted into the pharynx of every infant, when we are baffled in our diagnosis, for often here the cause of the disease is to be found.

There are two types of retropharyngeal abscess: (a) those occurring in infancy; (b) those in childhood and in adult life. In this paper I shall discuss the first class, the type found in infancy. The only resemblance that these two types have is that they bear the same name and are often found in the same location.

Simon, fifty years ago, demonstrated that in infants there exists a chain of lymph glands on the lateral wall of the pharynx, which drain the base of the skull and the nasopharynx. At the age of fifteen months these nodes begin to atrophy, and continue to do so until the age of three, when no trace of them is to be found. The cervical and submaxillary glands then assume the function of draining these areas. The retropharyngeal abscess of infants is an inflammation of the lymph nodes first described by Simon; in short it is a lymphadenitis, which usually goes on to suppuration.

The type occurring in childhood and adult life is not an inflammation of these glands. It is a spreading or burrowing of pus from some other source, as tuberculous disease of the spine, peritonsillar abscess, or submaxillary abscess.

That the medical world has been ignorant of the existence of such a condition until recent times, was demonstrated during a discussion of a paper by Dr. Roe on "Retropharyngeal Abscess." At that time, both laryngologists and pediatricians, admitted that they had seen but few cases. Henoch, a close observer, saw 60 cases in fifty years. A recent report of the Budapest Hospital for Children stated that 16 out of 1,000 cases admitted to that institution suffered from this disease. A report issued twenty years ago acknowledged but 2 in 1,000. I feel certain that the disease is no more prevalent to-day than it was twenty years ago. The other 14 cases were not diagnosed because of faulty technic in the examination. In the last five years I have seen 27 cases.

If we recall the statement that the retropharyngeal lymph nodes begin to atrophy at the age of fifteen months, one would expect inflammatory conditions of these glands to exist at the height of their activity. Holt says that three-quarters of the cases occur in the first year. Bokai reported 60 cases, 42 occurring in the first year. Snow, in 114 collected cases, reported 86 per cent. in the first year. Of my cases 21 were in children one year of age or under.

Contagious diseases, as scarlet fever and measles, are apt to be complicated with retropharyngeal abscess. In general, it may be said that 1 per cent. of scarlet fever and 0.5 per cent. of measles are followed by inflammation of these glands. Culture of the pus found in these cases invariably shows the staphlococcus.

Symptoms.—Occasionally there are no symptoms; spontaneous rupture, asphyxia, and death occurring without warning. The first symptom observed by the parents is usually difficulty in swallowing or breathing. In only 3 out of 27 cases I saw was the submaxillary adenitis the symptom that attracted the mother's attention.

The first sign, and the one that every case presents, is the submaxillary adenitis. Even before there is any swelling in the pharynx large enough to induce any other symptom, the adenitis already exists. The adenitis is unilateral, being on the same side as the retropharyngeal abscess. This adenitis is so typical and so characteristic that I make my diagnosis on the adenitis and then verify it by examining the pharynx. On examination there is a puffiness, but the skin is never red. On palpation the swelling is soft, never hard; the

glands are small and distinct, never matted together. The amount of swelling is out of proportion to the size of the glands, the latter being small, but the puffiness marked. There is a marked infiltration of serum in the periglandular tissue, this and not the enlargement of the glands causing the swelling in the submaxillary area.

The other symptoms that are usually present depend upon the location of the abscess. If it is situated in the nasopharynx the cry is nasal, the child snores, and has difficulty in breathing. When located in the oropharynx it may cause difficulty in swallowing. This may be due either to the pain of the inflammatory condition or to the mechanical obstruction by the mass. If the abscess is lower, about the epiglottis, the symptoms are hoarseness, stertorous breathing, and attacks of choking and cyanosis.

On examining the pharynx, the abscess can be seen only if it is located in the oropharynx; hence the absolute necessity of making a digital examination in every case, for often the abscess cannot be seen but only felt.

Diagnosis.—Always look for the submaxillary adenitis; there is no pharyngeal condition that will cause this particular and characteristic adenitis. Stenosed conditions of the larynx, whether catarrhal or diptheritic, may give symptoms that may resemble retropharyngeal abscess. The adenitis will be sufficient to help clear the diagnosis. I recently operated on an infant of nine months for adenoids. The diagnosis of retropharyngeal abscess had been made and on examination a large mass situated laterally was found. All the evidences, both from the sense of touch and from the symptoms, favored the diagnosis of abscess, but the absence of the adenitis ruled against this diagnosis.

Prognosis. — Retropharyngeal abscess unrecognized may result in death from asphyxia. The prognosis depends upon how soon after fluctuation is present the abscess is opened. Henoch reports a case of a professor, who had recognized a case of retropharyngeal abscess, but postponed the operation until the following morning so that he might show it at his clinic. During the night the infant died suddenly of asphyxia. Aviragnet reported a similar case. Bokai in a series of 317 cases reported 14 deaths, a mortality of 4.5 per cent. To-day the diagnosis being more promptly made, and surgical interference instituted the mortality is much lower.

Treatment.—The treatment is surgical. The abscess cavity should be opened as soon as fluctuation is detected. The incision, whether made by a scalpel, the tip of which only is exposed, or by the finger, which is the method I use, must open all pockets of pus.

The patient is seated in the lap of the assistant, the body of the infant is held firm. The mouth is then opened and kept open either by a tongue depresser held between the jaws or by the cheek of the patient pressed inward between the jaws. As soon as the abscess is opened the head of the child is bent forward to permit the pus to drain through the mouth and nares. By this method the pus and blood are prevented from entering the trachea and causing asphyxia. A mouth-gag should never be used to keep the jaws apart. Snow has reported a death following the use of this instrument.

1855 Seventh Avenue.

Medicolegal Notes.

Privileged Communications.—The Idaho Supreme Court holds that where a physician is employed to take an *x*-ray picture of a fractured arm, and helps to interpret the fracture, and advises with the patient's regular physician as to the treatment, such physician should not be allowed to testify as to facts learned by him during such employment, if the patient claims the privilege granted by the state statute.—Shaw v. City of Nampa, (Idaho) 171 Pac. 1132.

Practising Medicine Without License.—The Minnesota Supreme Court holds that the act of a person who styles himself a doctor, in receiving a patient who has applied to him for medical attention and examining him and diagnosing his ailment or disease and recommending an operation as treatment therefor, is practising medicine within the meaning of the Minnesota statute prohibiting the practice thereof without a license, though he prescribes no drug and administers no specific treatment to the patient.—State v. Rolph (Minn.), 167 N. W. 553.

Practice of Medicine Without a License.—An information following the language of the Missouri statute prohibiting the practice of medicine and treatment of sick, etc., without a license, charging that without license from the State Board of Health the defendant represented himself as authorized to practise medicine and surgery and to treat the sick and others afflicted with bodily and mental infirmities by offering to treat a certain person for ovarian disorders for a certain sum paid to him, contrary to the form of the statute, etc., was sufficient. There was evidence that the defendant held himself out as being authorized to treat the sick, or those afflicted with bodily or mental infirmities; that he maintained an office near the entrance to which was a large sign in the following language, viz.: "Evertz School of Suggestion. Oscar Evertz, S. D. Suggestionist. Treatment. Instruction;" that he circulated advertising matter concerning his method of treatment which is said to have been that of "auto-suggestion," and that he offered to treat the witness, Lennor Howes, in consideration of the sum of $45 to be paid to him in advance, and it was conceded that he was not a licensed physician. It was held that a violation of the statute was shown by this evidence.—State v. Evertz, (Mo.) 202 S.W. 616.

Insanity Defense—Questions to Medical Expert.—On a trial for murder where practically the only defense was insanity objection was made to a question asked of a medical expert on cross-examination: "Did you ever see a criminal who had an expressionless face?" The doctor had testified fully as to the appearance of the defendant, the condition of his skull, and had been examined in regard to his history and that of his antecedents. It was held that no harm was done by asking him if he had ever seen a criminal who had an expressionless face, as he answered "Yes." It was true that counsel should not have asked him the question, "If they had a family history of crimes and the grandfather had been a drunkard and epilepsy ran in the blood, and they had criminal tendencies, bank robbers, shooters, or what nots, and these descendants of such a race, when you come on down with them, you would find these fellows in the pen, wouldn't you?" The court did not think, however, that in the mass of evidence that was before it this mere question would have stood out and prejudiced the jury against the defendant, especially as the doctor answered that criminal tendencies were not inherited. An assignment of error objected to the question, "You all get mad out there on the farm sometimes, don't you?" It was claimed that the question had no bearing on the case. The court said that it probably had not, but it could hardly have been any more prejudicial than if the witness had been asked if he like all other men was not a miserable sinner.—State v. Mueller, North Dakota Supreme Court, 168 N. W. 66.

Military Medicine.

THE CRANIAL WOUNDS OF WARFARE.

Cerebral hernia is a common complication of penetrating cranial injuries when a more or less extensive attrition of the brain substance occurs. It is due to infection involving either the meninges or the cerebral substance, thus setting up an increase in the size of the contents of the cranial cavity and, therefore, hypertension of the cerebrospinal fluid. When the meningitis becomes generalized a hernia of the brain rapidly ensues. The dressings are soaked, the cerebrospinal fluid flows off in large amount, and when the wound is examined the hernia is seen. By slight pressure on its edges a decidedly purulent liquid is made to issue and when the overflow has taken place the hernia can be reduced to a certain extent, but always returns. The meningitis usually becomes localized, as the cerebral serosa possesses an extraordinary power of bacterial defense. A rather extensive area forms around the wound and in this false membranes become organized, forming a barrier against general invasion of the cranial content and then no more fluid will issue from the wound. For a cerebral hernia to form in these circumstances, the development of cysts in the false membranes must occur. The serosa will secrete into the cystic cavities, which slowly increase in size along with the increase of the hernia.

When the infection involves the cerebral substance an abscess will develop rather late in the wound evolution, but always coexists with a meningitis localized around the cranial wound, with or without cystic formation, but a localized meningitis may exist without an intracerebral abscess. In all these processes there must result a hypertension of the cerebrospinal fluid, a fact proven by the exit of the fluid under pressure when lumbar puncture is done, which is a dangerous procedure in these cases. Another proof is the reduction of the hernia after withdrawal of the purulent fluid in cases of generalized meningitis or after evacuation of the turbid serous liquid in meningeal cysts or after giving vent to the pus of a cerebral abscess. A diagnosis of generalized meningitis may be made by merely inspecting the dressings, and when a cerebral hernia exists for some time a diagnosis of its reduction can be made by finding the dressing pus soaked, which indicates that the cysts have broken down or that the cerebral abscess has been partially or totally emptied, after which the progress of the wound will be usually satisfactory.

Post Malarial Anemia.—Captains A. W. Harrington and W. Whitelaw, R. A. M. C., contribute a paper to the *Glasgow Medical Journal* of July, 1918, concerning the forms of anemia following attacks of malaria, observed and investigated by them in Macedonia. They found a great deal of post malarial anemia in that part of Europe, much of which was of a severe type. This occurred chiefly among Serbian soldiers, although occasionally among Bulgarians and other nationalities. From careful examinations and blood counts the following deductions were drawn:

Severe Forms.—(1) Post malarial anemia may assume a grave type characterized by all the signs and symptoms of pernicious anemia, but without evidence of oral or intestinal sepsis. (2) The spleen is enlarged, sometimes considerably so, but the liver is seldom enlarged. (3) The blood shows marked diminution of red corpuscles, high color index, leucopenia with a relative increase of lymphocytes, and to a lesser extent of large mononuclears, poikilocytosis, megalocytosis, polychromasia, occasional granular basophilia, the presence of megaloblasts and normoblasts, and a small percentage of myelocytes which persist. (4) Such cases occur most frequently as a sequel of subtertian malaria, but may follow benign tertian. (5) Recovery usually follows prompt and energetic treatment, but death may occur and the gravity of the prognosis increases with the age of the patient. (6) Treatment by arsenic used as in pernicious anemia, either as liquor arsenicalis in increasing doses or galyl or arsphenamine intravenously, usually leads to recovery. It should be combined with treatment by quinine, orally or intramuscularly, as indicated.

Mild Forms.—(1) The blood shows a less marked diminution of red corpuscles, a low color index, except in a few more recent cases, a less marked leucopenia with a relative increase of lymphocytes and large mononuclear cells; slight poikilocytosis, occasional megalocytes and polychronasia, rarely granular basophilia, the presence of normoblasts, and a small percentage of myelocytes frequently and of myeloblasts constantly. (2) The average age of the patients is lower. (3) Recovery is the rule.

Hygiene From the Soldier's Point of View.—In the *Dublin Journal of Medical Science* for July, 1918, Dr. W. F. Wicht discusses the personal hygiene of the soldier, pointing out that unless such hygiene is effective, an army will not be healthy and contented, and therefore will lose a great part of its potency as a fighting machine. In no war have the conditions been so difficult from the standpoint of personal hygiene as in the present war, and never before has hygiene gained so great a triumph.

Dr. Wicht emphasizes the need for personal cleanliness, and draws attention to the fact that the skin may be regarded as the first line of defence against disease, and states that the parts of the body that require special attention and should be washed every day, are (1) between the legs and buttocks, (2) the arm-pits, (3) feet and toes. Baths should be taken at least once a week if possible twice, or even more often. The hands should be washed before every meal, special attention being paid to the nails, as dirty nails are a common means of conveying infection. The hair should be kept short, should be brushed and combed daily, and washed frequently. A very important part of the body, which is only too often neglected, is the mouth. The mouth must be kept scrupulously clean, and the teeth cleaned, at least once, and if possible, twice daily, by rubbing with a brush. The best time for cleansing the teeth is immediately before going to bed; this removes all particles of food adhering to them after the evening meal. All decaying or painful teeth should be reported to the medical officer. The

mouth should also be washed out frequently with water.

Closely connected with the care of the skin is clean clothing. Dirty clothes foul the skin; and sweat and dirt from the skin soak into the clothes. For these reasons it is necessary that underclothes should be changed at least once a week. The same clothes should not be worn by day and by night. Socks especially should be changed frequently. Every man should try to have two pairs in use, one pair for morning and one for evening wear. If the socks are allowed to become foul and dirty, the feet very soon become soft and tender. If washing of clothes is found to be impossible, airing and exposing them to direct sunlight does a great deal of good. The sun's rays, if given time, will kill most germs, and also sweeten and freshen dirty clothes wonderfully. The hair-brush is an article which very easily becomes dirty. To clean this article rinse it, say, once every two weeks in a basinful of cold water to which a teaspoonful of washing soda has been added. Do not use hot water and soap.

Concussion Injuries of the Eye.—With regard to these injuries Ormond accepts Nettleship's view that, passing through the soft tissues, the force of a projectile is partly changed into vibrations which radiate from the track of the projectile. He thinks that such vibrations may pass through the bone without doing great damage and prove destructive in the soft tissues. He recognizes four ways in which the concussion effects are produced upon the eye: (1) By a missile traversing the orbits without rupturing the globes; (2) By vibrations, the results of blows upon the orbit and face transmitted to the interior of the eyes; (3) By vibrations transmitted from direct blows on the eye through the corneoscleral coat without rupturing it; (4) By vibrations the result of air pressure or windage.—Transactions of Ophthalmological Society of United Kingdom, 1917.

Statistics of Venereal Diseases in Troops.—Charlet and Bulliard publish in the *Annales de dermatologie et de syphiligraphie*, the statistics of 560 consecutive cases of venereal diseases treated during a period of eighteen months. The patients were from all services, active, reserve, territorials, Moroccans, and may be said to represent the entire army of the French. But a single geographical sector was represented and the troops were all men of the line. Very close to the sector was a large town which was far from being depopulated of civilians, for it sheltered from 15,000 to 20,000 of them. Aside from this place the civilian population was relatively small and scattered. The 560 cases comprised 153 of syphilis, 333 of gonorrhea, and 72 of chancroid. Of the total number 143 men were contaminated at the front—67 in the large town mentioned—and 417 in the interior. Of the latter 338 were on leave of absence. The men at the front were infected about equally by their "wives," who were largely of the common law variety, by public women, and by casuals personally known to them. The infections from public women were contracted in brothels. There are no statistics in reference to contaminations at the rear. Of the 153 syphilitics 38 were infected at the front and of the 333 cases of gonorrhea 98 were infected in the same area. But 7 cases of chancroid out of 72 were contracted at the front. There was not a single case of nonvenereal transmission, but there were 2 cases of extragenital chancre. To the 72 cases of chancroid are to be added 10 mixed cases with a total of 82 infections with Ducrey's bacillus. The percentage of contaminations at the front, which was about 25, agrees fairly with that of other observers. The authors are unfavorably impressed with the large number of cases of contagion out of control, for women out of the zone are of course practically unknown to the authorities and beyond supervision of any kind. Careful measures at the front are offset by the disastrous results of leave of absence. Of the 333 patients with gonorrhea 106 suffered from orchitis, 10 of which were double. Of the 72 cases of chancroid 14 were complicated with suppurating bubo.

Health of the Army.—The Surgeon General's health report for the week ended August 30 shows a slight increase over the previous week in the death rate from diseases among troops in the United States. There were 117 deaths during the week as compared with 94 for the week ended August 23. The sick or wounded soldiers from the American Expeditionary Forces landed in the United States during the last week numbered only 37 as compared with 423 for the preceding week.

Blood Transfusion at Australian Dressing Stations.—According to a cablegram to the New York *Sun* a regular system of blood transfusion has been adopted throughout the Australian dressing stations on the Western Front. It is stated that many men who otherwise would have died have, through this procedure, been enabled to stand an operation and have been put on the road to recovery. It is said that there is no difficulty in finding men who volunteer to give their blood for a comrade and often men with very slight wounds offer their blood for seriously wounded comrades.

Refuse Commissions for Doctors on Local Draft Boards.—Provost Marshall General Crowder has sent a letter to the Surgeon General's office requesting that commissions for doctors who are connected with local and district draft boards and medical advisory boards be refused until it is determined whether the doctor is not indispensable as a member of the selective service system. General Crowder points out that during the next few months nearly 14,000,000 men will have to be registered and hundreds of thousands examined, and that it is essential that the draft system be unhampered for the increased amount of work. The Surgeon General's office has replied that the present arrangement will render more than 18,000 medical men unavailable for commissioned service and it is suggested that some more economical method of examining registrants might be devised. Draft boards have been cautioned not to release any competent and necessary examiner until his case has been taken up at the executive chambers. General Crowder has also issued a protest against the practice of certain draft boards of sending

men who have been rejected at one camp for physical disability to another camp on a subsequent call, since this brings extra transportation expense on the Government.

Importance of Eliminating Mentally Unfit.—A cablegram received at the War Department from General Pershing states that the number of defectives received in recent replacement units in France suggests the importance of eliminating the mentally unfit from draft organizations before their departure for France. The War Department also complains that local boards have not always complied with the selective service regulations in sending men to camps where sleeping car accommodations are necessary en route. Failure of boards to issue proper Pullman or tourist requests has resulted in forcing many draftees to travel long distances in day coaches.

Another Hospital Bombed.—On the night of September 4 German aviators bombed a French-American hospital southwest of Soissons. Eighteen bombs were dropped, two of which struck the "red cross" on the lawn. There were no casualties, the patients having been removed to nearby caves when the bombing began. The hospital doctors relate with pride the bravery of the women nurses who went to and fro between the caves and the hospital during the raid to be sure that all the patients were under shelter.

Mount Sinai Hospital Reports on War Work.—The annual report of Mount Sinai Hospital, New York, shows that, in addition to caring for 9,983 patients at an expenditure of $695,859 at home, it is maintaining a base hospital in France which cost up to the time of its departure $100,000. Twenty-three doctors, 65 nurses, and 155 enlisted men are serving with this unit. Major Daily, M. C., U. S. A., is in command of the Mount Sinai Base Hospital Unit, known as Base Hospital Unit No. 3. Dr. Walter M. Brickner has succeeded Dr. Howard Lilienthal as head of the surgical department. The report calls attention to the large number of the attending and dispensary staff who are serving the Government in other directions, both in this country and in Europe. Members of the staff are also conducting classes for the training of medical officers.

No Longer a Shortage of Nurses.—The Committee on Nursing of the Council of National Defense announces that the nursing requirements of the American Army have been provided for and that there is no longer any shortage of nurses either here or abroad. In response to Surgeon General Gorgas's appeal for 25,000 graduate nurses 27,000 have already enrolled with the American Red Cross and of these 16,000 are actually in military service. A future supply of nurses will be assured by the Army School of Nursing established by the Surgeon General in connection with twenty-two of the military camps throughout the country. The appeal for high school and college graduates between the ages of 21 and 35 to take the prescribed course has resulted since June in more than 17,000 responses and more than 1,000 have actually been enrolled. Training units of from thirty to forty students have been sent to Camps Wheeler, Jackson, Sherman, Dodge, Shelby, Wadsworth, Devens, and the Walter Reed Hospital. Additional training units will be assigned to other camps within a few weeks. If it proves necessary quickly to augment the forces of nurses abroad, the plan is to send these students over at a suitable stage of their training and to allow them to complete their training while in service at the front.

Course for Hospital Aids Begins.—A special three months' course in bacteriology to train laboratory workers for immediate war service, began, on September 3, at New York University and Bellevue Hospital Medical College and also at other medical schools throughout the country. The courses have been undertaken at the request of Surgeon General Gorgas and arranged by Dr. William H. Park and Dr. Anna M. Williams.

Red Cross to Care for Captives.—The Atlantic Division of the American Red Cross has obtained two large storage houses at Copenhagen, Denmark, and at Renens, Switzerland, in which food, clothing, and other comforts will be assembled at once in sufficient quantity to maintain 10,000 American soldiers in prison camps in Germany, if that number should need care. During the month of July the American Red Cross extended aid to 372,835 civilians in France and 26,141 persons received treatment at the eight hospitals and seventy dispensaries maintained for the civilian population. During the week from December 16 to December 23 the Red Cross will hold a "Christmas Roll Call," at which it is hoped that practically every man, woman, and child in this country will become a member of that organization.

Lieutenant Harry A. Seigall, M. R. C., U. S. A., of Hartford, Conn., has been twice wounded during the performance of his duty as a surgeon on the Western Front, and is being cared for at the American Red Cross Military Hospital No. 3 in Paris.

Colored Doctors Appeal for Commissions.—The National Medical Association, with a membership of 5,000 colored physicians, at its annual convention in Richmond, Va., during the last week in August, passed resolutions deprecating the system of the War Department whereby, they claim, members of their race are not given a fair representation in the medical reserve corps of the Army and their nurses not allowed to care for colored soldiers on the battlefields of Europe.

Summer Nursing Course Ends.—Diplomas were awarded on September 9 to 418 young women who have completed their course at the Women's National Nurses Training Camp at Vassar College. These graduates will enter hospitals in various sections of the country for a two years' course in training.

Rest Houses for Nurses.—The American Red Cross plans to provide special nurses' recreation houses at all large base hospitals at a cost of $350,000. Contracts have been let for forty such homes. Several are already completed. The buildings are similar in architecture to the convalescent homes for soldiers, though smaller.

Nurses' Psychiatric Unit.—A special psychiatric unit of forty nurses has been assembled and outfitted in New York and will soon sail for overseas. These nurses have been specially trained to care for soldiers suffering from shell shock.

MESENTERIC EMBOLISM AID THROMBOSIS.

THIS condition has been considered very rare but is not so rare, actually, as the statistics of reported cases would make one believe; in fact, it is the making of the correct diagnosis that is the rarity rather than the condition itself. A very interesting and instructive article on this subject by Eisenberg and Schlink, under the title, "Mesenteric Vascular Occlusion," appeared in the July number of *Surgery, Gynecology, and Obstetrics*. They adopted this title for the reason that a definite symptomatological picture which would enable one to make a diagnosis of arterial rather than venous occlusion does not exist. They also consider that even the terms "thrombosis" and "embolism" are of no value clinically, since the most frequent source of a mesenteric thrombosis is an embolus. Tiedemann, in 1843, reported the first case of mesenteric vascular occlusion; and Trotter, in 1193, was able to collate 366 cases. Since that time 35 to 40 more cases have been reported, thus bringing the total to about 400 cases; yet Eisenberg and Schlink, during a period of only two months, had the opportunity of studying four cases. Their series makes a very instructive picture of the same condition being brought about by three different causes—acute infection, chronic infection, and injury. In two of the four cases the correct diagnosis was made before operation; in the third case the patient was operated upon for supposed intussusception; while the history of the fourth case is not given. To make the correct preoperative diagnosis in even 50 per cent. of the cases is doing remarkably well as compared with the records of previously reported cases; for of the 366 cases collected by Trotter, the correct diagnosis was made during the life of the patient in only 13, or approximately 3½ per cent. This, as the authors say, must be due to the fact that mesenteric occlusion is not thought of when considering the differential diagnosis of an acute abdominal condition.

The authors find that the occlusion is venous in about 40 per cent. of the cases, and in the majority of these both the superior and inferior veins are simultaneously involved. The common causes of venous occlusion are said to be descending portal thrombosis (usually due to sepsis or pressure due to cicatricial contraction of the liver), or more rarely a primary condition due to phlebitis resulting from an infectious process in the intestine (most often appendicitis). Arterial occlusion occurs in about 60 per cent. of the cases; the most frequent causes are emboli from the mitral or aortic valves, atheroma of the aorta, and pulmonary emboli.

Regarding symptomatology, the authors say that because of the various forms in which the disease appears it is impossible to outline a definite course. One factor to be emphasized is that the symptoms are the same whether they are due to arterial or venous occlusion. The condition may occur at any age. Legane mentions a case occurring in a child one month old; while the oldest reported case was that of a woman of 85. The majority of the cases occur between the ages of 20 and 60. The disease begins suddenly in most cases with attacks of colic or cramp-like pain in the abdomen lasting for five or ten minutes at a time and recurring after a period of equal duration, or the pain may be continuous. In all of the authors' four cases pain was the earliest symptom. In the majority of reported cases the pain has been generalized throughout the abdomen, being most intense usually about the umbilicus or in the epigastrium, or possibly in either hypochondrium or in the lower abdomen. Abdominal distention is a constant sign, usually appears early, and increases as the disease advances. Visible peristalsis is extremely rare. In only a few cases has a definite tumor been felt, palpation being so difficult by reason of the distention and the extreme tenderness. Gastrointestinal symptoms may be due to irritation, in which case diarrhea and melena preponderate, or they may resemble those of acute intestinal obstruction. The first vomitus consists of gastric contents, but later may contain blood. Usually the temperature is at first subnormal but may later rise to 104 or 105°. The pulse is generally that of a severe internal hemorrhage—small, rapid, and often irregular. Respiration soon becomes rapid and thoracic in type. The facies presents a combination of pallor and cyanosis.

The two chief reasons for the almost universal failure to make a diagnosis during life are first, the alleged rarity of the disease, and secondly, the extreme variation in the clinical picture. The signs and symptoms which the authors consider of the greatest importance in the diagnosis are: (1) Severe colic-like pain; (2) abdominal tenderness, tympanites, and occasionally shifting dulness; (3) rapid and excessive fall of tempertaure, associated with a weak and rapid pulse; (4) profuse melena with diarrhea followed by constipation; (5) persistent vomiting; (6) palpable tumor due to the mesenteric hematomata; (7) appearance of the patient

manifesting grave constitutional disturbances; (8) source for the embolus, *e.g.* endocarditis; (9) age of the patient, usually over 20 years.

Few patients have recovered under expectant treatment, and in these cases the correctness of the diagnosis is questioned. The form of treatment offering the greatest chance of recovery is immediate operation—the earlier the better—and doing whatever operative work necessary as rapidly as possible.

While cases in which the vessel occlusion is very extensive and a large segment of gut is sure to become gangrenous are hopeless from the start, there are many in which prompt operation offers a fair chance for recovery. It is impossible to believe that the condition is anything like so rare as the comparatively small number of reported cases would seem to indicate. The subject is an important one and we have devoted considerable space to its discussion for two reasons: First, that general practitioners as well as surgeons, when confronted by acute abdominal conditions of somewhat obscure origin, may keep the possibility of mesenteric vascular occlusion in mind; and, second, that those who see such cases may be induced to report them in detail so that the clinical aspects, especially, of this condition may be more generally understood and recognized. Certainly it is not creditable to the profession that but 13 out of a series of 366 such cases were discovered during the life of the patient.

MONOPHAGISM AND PELLAGRA.

THE term monophagism is sometimes used for a monotonous diet, although the word is somewhat misleading. The infant at the breast is a monophage, and the Scotch peasant who lives on oatmeal brose is another; yet neither appears to suffer from deficiency diseases. On the other hand, the child with a notable variety of diet who can be made to eat only a few dishes, and whose fickle appetite even refuses these at times, may not be monophagic, yet suffer from deficiency of certain foods.

The puzzling feature about pellagra is twofold. Not only is the diet monotonous but it is commonly believed that the maize is unfit for food. This question does not come up in the case of beriberi, for no one asserts that polished rice is not wholesome. Even in the scorbutic group, it is not claimed that the articles on which the patient subsists are unfit for food. It is therefore quite possible that there are two components to pellagra, viz., deficiency and intoxication. To throw light on this subject much experimental work is being done, and with the present food shortage the need of research is even more imperative than it was before the war. The scanty diets of the day are giving rise to new and unsuspected types of deficiency disease as well as to new types of food poisoning.

Animals have been poisoned with spoiled maize but the results obtained do not correspond to human pellagra. Experiments by Bezzola have even shown that sound maize as an exclusive diet may be fatal to animals. It has further been shown that an exclusive cereal diet is sometimes a cause of scorbutic symptoms. The vitamine theory has thus far failed to account for pellagra. Nevertheless, recent authors have been advocating the deficiency theory—which by the way is old, having been held as long ago as 1850 by Lussana. In this connection the American experiments are of interest, for these have shown that elimination from the diet of meat, fresh vegetables, etc., is followed by pellagroid symptoms.

In some of the recent experimental work in Italy attempts have been made to isolate certain components of the disease. Thus Volpino in the *Annali d'Igiene* for May 31 has studied especially the hypersensitiveness of the disease. A sterile extract of spoiled maize was first injected into pellagrins in accordance with a technique which has been in use for some years. In nearly all of the subjects a peculiar reaction was set up. In a few cases the latter was severe in type but in all of the cases it subsided in a few days. The first symptoms to be mentioned were stupor and somnolence with amnesia. Tremor was marked. Of general symptoms which accompanied the neuroreaction nausea and malaise may be first mentioned. The temperature rise may be considerable and the erythematous areas show increased redness. The reaction was next studied in controls and no less than 23 nonpellagrins were injected with the extract of spoiled maize. In 19 the only reaction was a slight rise of temperature. The other four gave the pellagrous reaction. These men were at once examined for evidences of the disease. The first patient had Banti's disease but bore no signs of pellagra. He had, however, lived on maize since childhood, eating it at least twice a day. There could be little doubt that he had eaten spoiled maize in his time. In the other cases nothing was found to throw light on the reaction. Although the author states that the latter was specific he adds that the neuroreaction shown by the pellagrins was absent. In this difference the author sees evidence of a strong predisposing factor—the pellagrin becomes such because of a nonresisting nervous system. Without this nerve component the subject does not develop the disease, at least in its pernicious form. There is, however, a question of acquired immunity—those who escape the disease may do so because of the development of protective antibodies.

SMALLPOX AND FLEAS.

IN a country like Brazil contagious plagues take on new significance. Most of the country is tropical, and it is said that vaccines do not keep well in hot climates, and consequently give inadequate protection. Local scientists are therefore interested in other forms of prophylaxis than those which obtain in temperate climates, and in the actual manner of diffusion during an epidemic. If carriers can be proved to be active then mere personal contact and fomites will be less in evidence, and isolation, disinfection, etc., must be carried out along different

lines. In the *Brazil-Medico* for December 29, Ferrari of the Rio smallpox hospital relates some experimental work done by himself and Meirelles, the latter an industrious student of variola. As soon as a new case is received six questions are put which cover the subjects of vaccination, known exposure, proximity, sleeping place, and the presence of fleas in numbers. In 24 per cent. of these groups and during a certain period there had been a case of the disease in the dwellings; in 22 per cent. the patient had been exposed to a case outside his own residence; in 70 per cent. there were domestic animals in the house; the number vaccinated was 51 per cent., successful in less than a third; those who slept on rugs and mats numbered 44 per cent., while 38 per cent. complained of fleas.

It becomes at once evident that the majority of victims had not been knowingly exposed to the disease, and the writer suggests that the disease is not improbably spread by the agency of fleas. One argument in support of this is that a mild case will often beget a malignant one in the same household, this sudden increase in virulence being attributable to passage of the organism through fleas. Again, it has been claimed that in certain towns in which the houses have cement floors epidemics of variola have never occurred. In Santiago, Chili, many unvaccinated prisoners in the House of Correction were vaccinated on admission. But of the 700 inmates many had never been vaccinated. Presently a very severe epidemic of variola broke out among the poor of the city. The prison was equipped with smooth cement floors, which were kept sterile. No cats or dogs were allowed on the premises, and the prisoners' clothing was kept fumigated. Not a single case of variola developed in the prison, and the non-vaccinated prisoners must in part have been protected by some of the prophylactic measures employed. The authors clearly believe in antiflea measures.

LEPROSY.

Leprosy is known to have been cured by intercurrent diseases, among which are erysipelas and high continued fevers, notably variola. The inference in such sequences is that Hansen's bacillus cannot survive a certain temperature maintained for a certain period. So far as we know, however, no one has as yet made any systematic use of hyperthermia in the treatment of the disease. One reason for this omission may be the fact that intensive and prolonged treatment with chaulmoogra oil by intramuscular injection will occasionally bring the disease to an arrest if not a cure. But it must not be forgotten that leprosy not infrequently undergoes a spontaneous arrest, so that not much can be inferred from the outcome of any single case. Of two formulas in use in leper asylums, that of Jeanselme is said to be superior to the one known by Mercado's name. Both contain chaulmoogra oil and camphor. The former also contains guaiacol and the latter resorcinol. Originally, chaulmoogra oil was used externally and by the mouth, but its reputation as a specific has been greatly enhanced since it has been administered by the subcutaneous, intramuscular, and intravenous routes. An offshoot from this treatment is the use of the alkaline salts of gynocardic acid, as reported by leprologists in the Philippines and in Hindustan. Bacteriological control is used, and a slow sterilization appears to be demonstrable.

In the April number of the *Cronica Médico-Quirúrgica*, Dr. López Silvero brings out the above facts. Dr. Ribón of the Agua de Dios leper asylum in Bogotá has recently placed on record numerous cases of cure of leprosy, as a result both of intercurrent disease and of treatment. The average duration of treatment with intramuscular injections is placed at two years, after which interval patients may be bacillus free.

Dr. Cabrera of the Rincon leper hospital in Havana recently delivered an address before the Society for Clinical Study on the so-called Garcia plan of treatment which had been much discussed in the popular press. It is apparently a decoction of miscellaneous herbs, used as an adjuvant to chaulmoogra oil to mitigate its disagreeable action on the stomach. Hot baths are also part of the treatment, which may represent a reaction against the use of the oil by the syringe. A committee of prominent Havana physicians, appointed to investigate the Garcia treatment, found the bacillus in the lymph and mucosities of patients under treatment by the Garcia method while the results were in no wise superior to the general sum of those under the usual treatment.

Intellectuals and the War.

The world is upside down and it will take a long time for conditions to revert to normal. Indeed, such radical changes have been effected in so many directions that life will probably never again be the same. In the *Glasgow Herald* a few weeks ago there was an article dealing with the effect of army life upon the intellectuals. The writer argues that military service tends to intellectual atrophy and believes that many of these men of brain and culture will be quite unable after the war to carry on the work in which they were formerly engaged. The first lesson the intellectual has to learn in the army is that of complete subservience of mental faculties. He has to reason but to reason along stereotyped lines. He loses the independence of thought to such a degree that the reasoning becomes in the worst sense mechanical, which is intellectual stagnation and even death. The day of the soldier is filled with mechanical work, the mind atrophies, stimulation is lost, and intellectual interests are deprived of their grip. Physical exhaustion plays its part until the victory of matter over mind is complete. The craving for relief from the benumbing routine of work becomes intense and takes the form of an overpowering desire for sensuous pleasures. As a matter of fact, mental work is almost impossible among the surroundings of trench life and mental apathy supervenes. The entire system of army service is hostile to intel-

lectual life and frowns upon any attempt to exercise the reasoning powers except within very narrow limits. If, then, military life is inimical to intellectual life and renders the reasoning faculties torpid, the question arises, Can men of brains who have been thus affected "come back"? The writer whose views we have quoted appears to be pessimistic regarding their ability to do so. He thinks that, as a rule, their powers of mind have been virtually killed or so greatly inhibited that they will require very careful treatment in order to be enabled to recover. They will have forgotten much that they knew and will have to begin over again to a large extent. Therefore, ambition must be revived in them and their minds must be stimulated to regain an interest in matters which have become alien to their thoughts. There may be a little truth in what the writer says, but he takes altogether too black a view of the intellectual who has fought in the war. Although he will never regard life with the same eyes as formerly, his mind will have been stimulated rather than blunted and he will come back more of a man, mentally and spiritually, than he went in, and his views of life and its problems will be widened immensely.

The University of Athens and the War.

In the July issue of the *Journal de Médecine de Bordeaux*, Dr. Portmann, a naval surgeon attached to the French Legation at Athens, writes entertainingly on this topic. The University of Athens, he says, is regarded as the principal center of culture in the Orient. Its influence is felt in Egypt, Asia Minor, and the regions northerly to it; or, broadly speaking, through the entire eastern basin of the Mediterranean. Students from this combined area return home and disseminate the modern Hellenism. Originally this was based largely on French culture, but in the course of time the Teuton in his "Drang nach Osten" found in Hellenism a stumbling block and set about to remove it. His task was to supplant a Greco-Latin by a German civilization. In this movement he had the support of Greek royalty. At the beginning of the war the movement was just bearing fruit. Empty chairs were filled with Germans and Germanophiles. The students were advised to complete their studies at Bonn, Breslau, and Munich. The cause was already half won and many returning graduates were proclaiming German superiority throughout the Orient. This was true particularly of the medical students, who come into the most intimate contact with the people. The Medical Department of the University of Athens became saturated with Teutonism and the hospital staffs seemed to consist largely of men with German diplomas. At this juncture Venizelos took a hand in the game and sixteen professors, of whom seven belonged to the medical faculty, were released from their duties. At the same time the French graduates organized themselves into a Franco-Hellenic movement. Two new medical societies were organized and three periodicals were begun to aid the movement. Professors were exchanged between French universities and the Greek institution. It soon became apparent that the German bluff had been called. Greek medical students are in the French army and when the war ends many will be graduated from French universities. The French culture is betted suited to the genius of the race than the mechanical methods of the Teuton. The Philhellenist and the Francophile will not perish from the earth to make way for the Hun.

Physiology of the Rectosigmoid Intestine.

Bufaloni, writing in the *Rivista critica di clinica medica* of May 4, says that the abdominal viscera are innervated by the sympathetic in association with fibers from the central nervous system, the whole forming an autonomous system, the center for which is the lumbo-aortic plexus. The intestine proper is insensitive to pain and the sigmoidorectal mucosa shares this insensitiveness until we come to the lowest segment of the rectal ampulla. The painful sensations in volvulus, etc., are derived from the peritoneum and mesentery while spasmodic pains proceed from the muscles. The pain in rectal tenesmus is present because of the above mentioned sensitiveness of the lowest rectal segment and that of the musculature. The sensitiveness of the anal canal is intense and persists for a space of 4 to 5 cm. above the internal sphincter. The muscle tonus in the sigmoidorectal segment is permanent and serves to retain the fecal bolus in the sigmoid from one evacuation to the other. If the tonus is increased spasticity is the result, and, if diminished, atony. In a spastic gut the bolus is compressed into a ribbon, while in an atonic sigmoid it is pasty and shapeless. The muscle tonus is not sufficient to cause defecation, for this purpose peristalsis is superadded. Antiperistaltic movements also occur, for example when a subject neglects a call of nature and also whenever there is an obstacle to evacuation. The physiology of the rectosigmoid includes the power of absorption of food, as utilized in rectal alimentation. This segment of intestine secretes sufficient mucus to lubricate the fecal cylinder for its passage through the anus. The usual duration of passage from stomach to sigmoid is 18 hours; during this period the food residues reach the sigmoid and undergo dehydration, so that 24 hours usually elapses from breakfast to defecation. It is the contact of the fecal mass with the sensitive area of the lower rectum which causes the summons for defecation. The latter usually follows a meal (breakfast), because the latter excites peristaltic waves.

News of the Week.

The Volunteer Medical Service Corps.—The Council of National Defense announces that many thousand blanks for enrollment of the legally qualified men and women physicians of the country in the reorganized Volunteer Medical Service Corps are being mailed by the chairman of the General Medical Board of the Council of National Defense. With the blank are enclosed a letter and a folder giving all details as to the organization.

The Volunteer Medical Service Corps organization provides means for obtaining quickly

men and women for any service required; furnishes recommendations and necessary credentials to assure the best of medical service, both military and civil, and determines beyond question the attitude of the individual toward the war. The object of the corps is to place on record all medical men and women in the United States; to aid the Army, Navy, and Public Health Service in supplying war medical needs; to provide the best civilian medical service possible, and to give recognition to all who record themselves in Army, Navy, Public Health activities, or civilian service.

Under the reorganization, every legally qualified physician, man or woman, holding the degree of Doctor of Medicine from a legally chartered medical school, who is not now attached to the Government service, and without reference to age or physical disability, may apply for membership and be admitted if qualified; the original organization admitted only those who for various reasons were ineligible to membership in the Medical Reserve Corps. The organization will mobilize the medical profession in order to provide for the health needs of the military forces and the civil population, and the recording and classifying of doctors will afford means of obtaining quickly men and women for any service required.

To date about 40,000 of the 144,116 doctors in the United States—not including the more than 5,000 women doctors—either are in government service or have volunteered their services. Up to July 12 the Surgeon General had recommended to the Adjutant General 26,733 doctors for commissions in the Medical Reserve Corps. About 9,000 others who applied were rejected. With the 1,194 in the Medical Corps of the National Guard and 1,600 in the Navy, the total, 38,527, constitutes 26.73 per cent. of the civilian doctors. Deducting those who declined their commissions or who have been discharged because of subsequent physical disability or other cause, the number actually commissioned in the Medical Reserve Corps stood on August 23 at 23,531, with several hundred recommended whose commissions were pending. Of the 23,531 there are 22,232 now on active duty. It is estimated that at least 50,000 doctors will be necessary eventually for the Army. It can readily be seen that with the enrollment of these active men their places in communities and institutions must be cared for and the work, therefore, throughout the country must be so systematized and coordinated that the civilian population may not suffer. An important aspect is the need for medical men in the communities where munitions and other vital war products are being made. The Volunteer Medical Service Corps, supervised by the Central Government Board, will thoroughly care for these needs.

Influenza on Liner Causes Two Fatalities.—A liner arriving at an Atlantic Port on September 4 was detained at quarantine on account of an outbreak of influenza. There were in all twenty-five cases of the malady during the voyage. Of these two developed pneumonia and died at sea. The remainder have been removed to a local hospital.

Marriage and Fecundity of College Women.—A recent statistical report on 16,739 graduates of women's colleges in the United States shows that 39 per cent. were married. It appears from this report that employment affects marriage, for of the total number who have been gainfully employed only 39.5 per cent. were married. Of the married graduates 69.9 per cent. had children, averaging 2.1 per family. One Wellesley graduate reports eleven children, and for none of the colleges was the maximum number less than six. In the entire group of married graduates 29 per cent. had three or more children. In connection with these figures the fact is to be taken into consideration that many of these women are still young and their families are not complete. It is observed that the mortality among the children of college women is low. Of all the children born to women included in this census only 6.7 in every hundred had died and only 4.5 per cent. had died during the first year. The figures of the Federal Children's Bureau show that in Manchester, N. H., and Johnstown, Pa., the infant mortality rates were 16.5 and 13.4 respectively, and in a residential suburb in New Jersey where living conditions were of the best the rate was 8.5 per hundred.

Nurses Needed for the Insane.—The New York State Hospital Commission announces that 1,000 young women are needed in State hospitals for the insane to replace nurses and attendants who have gone into national service. The New York State Hospitals have arranged with the Federal Government to receive all mental cases developing in citizens of the State with the army and navy forces. A considerable number of such cases have already been received and the number is constantly increasing. The State hospitals also train male nurses and applications are invited from men who are available for military duty. Training school classes for a shorter course of instruction for attendants, covering about six months, will be started October 1. Further particulars in reference to this course may be obtained from the State Hospital Commission, Albany, N. Y.

To Aid Needy Professional Men.—The will of Michael J. Dunn of Springfield, Mass., provides the nucleus of a trust fund which when it amounts to $100,000 is to be devoted to assisting the education of needy professional men. The Springfield Lodge of Elks is to administer the fund.

Civil Service Positions.—The New York State Civil Service Commission announces the following examinations to be held on October 5, 1918. Assistant Serologists, at a salary of $2,000, open to men and women between the ages of 21 and 35 years. Candidates should have a college education or its equivalent. Assistant Bacteriologists, at a salary of $1,200 to $1,800, open to men and women. Training and experience in sanitary chemistry are desirable for this position. Bacteriologist-Pathologist, at a salary of $2,500, open to men and women between the ages of 25 and 40 years. A degree in medicine or an equivalent education in a college maintaining a standard satisfactory to the Commission, and training and experience in chemistry are desirable though not essential. Laboratory Assistant in Bacteriology, at a salary of $720 to $1,200, open to men and women, between the ages of 21 and 30. Only candidates who have satisfactorily completed a course in bacteriology will be accepted. Laboratory Ap-

prentice, State Department of Health, at a salary of $600 to $720, open to men and women between the ages of 21 and 30 years. Physiological Chemist, at a salary of $1,500, open to men and women between the ages of 21 and 35 years. A degree from a college maintaining a standard satisfactory to the Commission is required. Assistant Physician, regular or homeopathic, at a salary of $1,200 with increase, open to men and women who are licensed practitioners of medicine in this State. Application must be in the hands of the Civil Service Commission, Albany, N. Y., not later than September 25.

Dr. Edward Fauver of Middletown, Conn., has been appointed football coach at Wesleyan University for the coming season.

Prague Decimated by Disease.—A report submitted by the sanitary officer of Prague to the City Council shows that in 1913 the number of children born alive was 3,274; in 1917 the number dropped to 1,718, or in other words there was a decrease of 48 per cent. in the birth rate. At the same time the number of deaths increased from 3,000 in 1913 to 3,828 in 1917. Thus there were 2,115 more deaths than births in 1917, causing a reduction in the population of 6½ per cent. Most numerous among the causes of death is tuberculosis, which has caused from 18 to 25 per cent The report states that the sanitary condition of the city is deplorable. Much of the report has been suppressed.

Monument to Oswaldo Cruz.—A monument is to be erected in some one of the public resorts of Rio de Janeiro to the memory of the distinguished hygienist, sanitarian, and bacteriologist, Oswaldo Cruz, founder of the institute which bears his name and which corresponds to the Pasteur Institute of France, and similar institutions in other countries. The design, which has been approved for the memorial, was recently published in the *Brazil-Medico*. Aside from a large sum subscribed by the Government of Portugal the names of subscribers to the memorial are exclusively those of Brazilians, either individuals or societies. State governments, banks, college faculties, and other bodies of men are represented, as well as numerous hospitals.

Obituary Notes.—Dr. Frederick Henry Cleaves, a graduate of George Washington University, Washington, D. C., in 1887, died at his home in Boston, Mass., on August 21. He was acting assistant surgeon in the United States Marine Hospital Service, in which capacity he served in the out-patient department at the customs house at Boston for eighteen years. He was also the medical examiner for the Union Mutual Life Insurance Company of Maine.

Dr. Robert John McFall of Paris, Tenn., a graduate of Vanderbilt University Medical Department, Nashville, Tenn., in 1892, was run over and instantly killed by a railroad train near his home on August 15. Dr. McFall was 53 years of age.

Dr. Andrew J. Osborn of Lawrenceville, Va., a graduate of the Medical College of Virginia, Richmond, in 1899, died in a local hospital on August 8, aged 49 years.

Dr. Rebecca Moore died at Kennett Square on August 26, at the age of 83 years. She was graduated from the Woman's Medical College in the class of 1883.

Dr. William Merrill, a retired physician, who practised many years in Portland, Me., died at his home in that city on Aug. 16, aged 85 years.

Dr. Charles J. V. Fries died of apoplexy at Philadelphia, on August 30, at the age of 55 years. He was graduated from Hahnemann Hospital and Medical College in the class of 1894.

Dr. Harry F. McKay died of arteriosclerosis at his home in Portland, Ore., on August 24, aged 56 years. He was a graduate of Willamette Medical Department in 1895, and for the past six years had served on the State Board of Medical Examiners.

Dr. James MacKellar of Hazleton, Pa., died in a hospital at Philadelphia on August 31, at the age of 54 years. He was graduated from the Medico-Chirurgical College in 1891. He was a member of the Luzerne County Medical Society, of the Medical Society of the State of Pennsylvania, and of the American Medical Association. He was a member of the Hazleton Exemption Board.

Dr. Cornelius Van Riper of Passaic, N. J., a graduate of the University of New York Medical College, in 1866, died at the residence of a relative in Jamaica Plain, Mass., on August 20, aged 77 years.

Dr. John A. Chard, a graduate of New York University Medical College in 1897, died at his home in Jersey City, N. J., on August 30, aged 54 years.

Dr. Alexander McLean Jeffrey of New York, a graduate of New York University Medical College in 1896, died following a stroke of apoplexy at his summer home at Mt. Kisko, N. Y., September 2, aged 59 years.

OUR LONDON LETTER.

(From our Own Correspondent.)

PUBLIC HEALTH AND POLITICAL PROGRESS—COMPULSORY EXAMINATION OF WOMEN FOR EVIDENCES OF VENEREAL DISEASES—CHANGES IN THE INDIAN MEDICAL SERVICE—THE PERILS OF SMALLPOX.

London, August 16, 1918.

The position of Ireland is, for obvious reasons, an extremely embarrassing one, not only for Great Britain but for all those nations who are fighting for the Allied cause against the Central European Empires. Especially has it difficulties for the United States of America, where Irish national aspirations have received such generous support. Fortunately—for the task would be indeed a difficult one—there is no onus in a medical paper to discuss political questions. I need make no attempt to evaluate how far bad government by Great Britain, or religious prejudices and antiquarian sentiment in Ireland, manufacturing greed, agrarian ignorance, or treacherous interference by Germany with Irish politics, have played a part in the confusion which exists, but one factor in that confusion has a distinctly medical significance and that is the abominable condition of public health in Ireland. The rural districts of Ireland are cared for medically by the officers of the Irish Poor-law Medical Service. These doctors, too often chosen for their posts for other than medical reasons, are overworked, ill-paid, un-

supplied with material assistance in such matters as hospital and laboratory accommodation or expert and consultant opinion, and are unable to afford to the districts in which they practise any medical care comparable to what might be expected in an integral part of the British Empire in the 20th century. Ireland is to-day a sparsely populated island, and, despite its enormous potential wealth, notably in the direction of agricultural and fishing industries, the population is a poor one. The significance of this is that the officers of the Irish Poor-law Medical Service cannot expect any substantial addition to their official salaries from the fees of private patients. Here, however, it may be said that Ireland is not much worse off than many parts of Scotland, or some of the more sequestered districts of England. Again, it may be admitted that general public health organization and administration matters less when a population is small—to reduce this point to absurdity there is no central drainage or water scheme required in the Sahara Desert, because the number of persons who would benefit by the innovations is not large enough to warrant the expenditure. But Ireland is not at fault in public health administration only in its rural regions; of its great cities the same story can be told, and here we can note a most serious effect on the birth-rate, sick-rate and death-rate of the country, which may well be playing a serious part in promoting the political unrest. While, for example, the birth rate of London, with a population of over four millions, was, in the first week in August, only 11 per mille, that of Belfast was 15 and of Dublin nearly 16. In both the great Irish cities the expectation of life at all ages is terribly below what it should be, while the infantile mortality is correspondingly heavy. From a medical point of view it stands to reason that if these two cities, in which are concentrated the two representative classes of political thought, enjoyed a higher standard of public health, political questions would be approached in a far more wholesome manner. Therefore, the submission of a great housing scheme for Dublin is an important event to the whole British Empire and our Allies, for in a more healthy Dublin politics will be discussed with less rancour. Dublin is a great medical center, where the men of our profession have enjoyed for many generations high prestige as exponents of their calling in every division and specialty. The public health of their city has been the despair of the doctors, for it is impossible to keep down the ravages of such diseases for example as tuberculosis and infantile diarrhœa when the population lives in a perpetual environment favorable to the incubation and spread of pathological conditions. Dublin medical men, therefore, will share with particular keenness the delight of all thinking people in learning that the Engineering Inspector of the Irish Local Government Board, Mr. P. C. Cowan, has submitted to the Chief Secretary in Ireland a scheme for dealing drastically with the rehousing question in Dublin. Mr. Cowan's scheme will entail an expenditure of from eight to nine millions of State money, for he sets out the necessities of the case as follows:

"Sixteen thousand new self-contained houses to prevent overcrowding and to permit the separation of the sexes; the improvement by remodeling of 3803 first and second-class tenement houses, in which 18,991 families now live, so that the total number of remodelled houses may afford suitable accommodation in tenements of from one to four rooms for 13,000 families. The figure of 16,000 is adopted as the number of new houses that are required to-day. These houses, if built in continuous rows on each side of a street, would be 25 miles long. The houses should be erected by a board representing the Government, the city of Dublin, the urban districts, and the Dublin County Council. The board should not exceed 11 in number, and should hold office for 10 years. Mr. Cowan estimates the expenditure, it will be seen, under two headings of rebuilding and reconstruction. The 16,000 new houses, at £400 each, makes a total of £6,400,000, which the acquisition and reconstruction of old tenement houses should cost, he thinks, £2,040,000. Those who do not know what a distinguished city Dublin is, may be surprised at the possibility of acquiring within its boudaries nearly 4000 houses which could possibly be adapted by reconstruction to the purposes of a central sanitary scheme. But Dublin, as a matter of fact, is full of magnificent houses quite capable of intelligent alteration, for Dublin was once a great and profuse capital. If Mr. Cowan's scheme is carried out a vast improvement must occur in the public health of the city, and by the removal of a visible reproach to British management political progress will be served.

The regulation under the Defence of the Realm Act ("Dora"), commonly known as "Dora 40.D," which orders the compulsory examination of women, in certain circumstances, for evidences of venereal diseases, has now been in force for some time, and all classes of the community are coming to the conclusion that its value as a measure of public health has been disappointing. The regulation was desired, it must be remembered, as a measure of public health, and not either to protect the fornicator or to punish one party in the commission of fornication, the form of the instruction running thus: "No woman who is suffering from venereal disease in a communicable form shall have sexual intercourse with any member of H. M. Forces, or solicit or invite any member of H. M. Forces to have sexual intercourse with her." Now, if it is found difficult to bring evidence sufficient to satisfy a legal tribunal that a particular woman has a venereal disease in a communicable form the regulation is likely to fail in its purpose; but if it should be doubtful whether Adam infected Eve or *vice-versa*, the prosecution of Eve must fail. And there is no machinery for prosecuting Adam, even if Eve were a member of one of the women corps cooperating with H. M. Forces. The National Council for the Prevention of Venereal Diseases, recognizing these difficulties, as well as the fact that attempts to secure convictions against women, even when the poor pathological grounds were reinforced by all the arguments of probability, have failed in a large proportion of the cases which have reached a legal tribunal, are now advocating the rescinding of 40.D.; and their view will be largely supported, though the commanding officers in big camps will not be pleased. The case here is so different that it should not baffle official ingenuity to meet the special difficulties. As a general measure 40.D is open to two main objections: (1) diagnosis, (2) allottment of responsi-

bility. The vagina, cervix, and especially the urethra contain lurking places which the bacteriologist, save with the most rigid inspection and prolonged investigation, cannot safely pronounce to be free from communicable mischief; coitus is a more thorough test than bacteriology, and again the woman may be uninfected but a temporary carrier. Secondly, the infected man may not have acquired the germ from the last coitus, to which inevitably he attributes his trouble, but to a previous adventure; while if the examination of the woman, which is proved positive, is not made immediately, what is to prove that the sufferer, alleging her guilt, may not himself have infected her, being, unknown to himself, in an infectious condition before their embraces? But this is not to say that nothing should be done to rid the neighborhood of great camps from the molestation of prostitutes, any of whom may be the focus of infection for a large number of susceptible men. It is the commanding officers of such camps, witnessing the sick-rate from a preventable disease wasting their numbers daily, who demand a legal remedy, and who do so on very good grounds. There is every reason to suppose that if 40.D is rescinded, because of its futility, regulations will be provided for dealing with the mischief in its grosser and more concentrated forms.

Small measures of reform in the Indian Medical Service are constantly announced, and are received not so much with gratitude, as with a feeling that they may prove to be an earnest of far greater changes in the future. There have just been created, for the period of the war only, eight important administrative appointments in the Service, which will be filled by officers holding the rank of or promoted to the rank of colonel, and by selection in accordance with circumstances. Colonels in the Indian Medical Service, after active service in that rank, are eligible for a substantial addition (£250 per annum) to their retiring pensions, and the new appointments are to carry the same privilege.

With all our admitted progress, in every civilized country in the world, in the realm of sanitation and preventive medicine, we cannot afford to ignore the only prophylectic known to science as yet against smallpox—namely, vaccination and revaccination; yet this country now contains many thousands of unvaccinated children, and adults who have received no protection since their infancy, or who are now in a condition of more or less modified susceptibility. The presence of a world war must make this situation a thoughful one—at any rate for medical men, and those who think. Smallpox is present in every quarter of the globe, while an enormous admixture of peoples and races and languages is taking place as a result of the war. Prisoners are being taken on one front who have recently arrived from another; populations are being deported; wanderers and refugees of the poorest classes are finding their miserable way from one hideous refuge to another, and all these people may have emerged from, or may be journeying to, places where an attack from smallpox is a likely event. We have, therefore, the fire laid for a fierce conflagration; it may burst out anywhere, and our sanitarians ought to be prepared. In a report to the English Local Government Board which has just been published, Dr. Bruce Low, one of the Medical Inspectors of the Board, gives a detailed account of the behavior of smallpox in almost every quarter of the globe, and in sounding a warning note as to the dangers that may arise in England, calls pointed attention to the fact that the Franco-German war, forty years ago, was followed by a disastrous epidemic of smallpox, which spread over the whole of Europe, and which caused half a million deaths, ten per cent of this hideous mortality occurring in England. With such battle-fronts as are now concerned, in comparison with which the areas involved in the Franco-German war are quite tiny, the risk not only to England but to the United States is great, and should smallpox get a hold in either country the consequences might be disastrous, for many of those experienced medical men, who could be trusted to put down an epidemic with promptitude, are absent from their local duties. In the present day many of the younger generation of British medical practitioners are unacquainted with smallpox; they might fail to diagnose it, and could be pardoned if they did not at once take the right steps to stamp out an epidemic. But none of these things affect the serenity of a public reassured by the comparative disappearance of the disease from among us. May there be no rude awakening!

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

RED CROSS LIFE AND HEALTH INSURANCE—AMERICAN RED CROSS IN ITALY—DR. STRONG OF HARVARD RECEIVED AT THE ACADEMY OF MEDICINE.

PARIS, July 30, 1918.

THE American Red Cross has arranged for the furnishing of life, health, and accident insurance to its own workers abroad who are not eligible to the benefits of government war risk insurance. All foreign workers are to get free of cost and without medical examination $1,000 life insurance on the term plan, payable in event of death or at the end of two years, in event of total and permanent disability, and also accident and health insurance providing for weekly indemnity payment in case of disability from sickness or injury. All foreign workers are also to have the privilege of buying additional life insurance on the ordinary life plan with medical examination, up to a total of $5,000—including the $1,000 above mentioned. The worker will pay the regular normal premium on the same and the American Red Cross will assume the extra war risk premium. In its efforts to secure the best solution of this problem, the Red Cross War Council appointed a committee of the Actuarial Society of America which, in cooperation with Robert C. Rathbone, director of the Red Cross Insurance Bureau at Washington, prepared and recommended this plan of insurance. An adjustment office will be established in France and the general administration of the insurance will be conducted from the Red Cross Insurance Bureau at Washington. The Red Cross workers are not eligible for the benefits of government war risk insurance unless actually enlisted in the U. S. Army or Navy, therefore the insurnace plan announced by the Red Cross is a most important relief measure for its own workers, many of whom

are voluntarily serving abroad at great personal sacrifice.

Dr. William Charles White has resigned as chief of the Bureau for the Care and Prevention of Tuberculosis of the American Red Cross. He is succeeded by Dr. Donald E. Baxter, who has been the assistant chief of the Bureau of Tuberculosis since its formation and was associated with Mrs. Wharton's work, "Les Tuberculeux de la Guerre," before the Red Cross Commission came to France. He is returning to his duties in Pittsburgh, where he is professor of the faculty of medicine in the University of Pittsburgh.

Mr. Rudolph Reeder has been assigned assistant chief of the Children's Bureau, in charge of all matters relating to the care of destitute children, juvenile delinquents, trade instruction, and similar non-medical matters. Before coming to France, Mr. Reeder was superintendent of the New York Orphan Asylum at Hastings, N. Y. He was a pioneer in the development of the cottage system for children's institutions in America and in getting needy children established in occupations or professions. More than fifty of his former charges are now in the American Army.

The American Red Cross has issued a report summarizing the work done during the first five months in Italy. Although the report gives figures, it adds: "It is impossible to convey by statistics even more imporant results—results which may be measured only by the present universal spirit of brotherhood and sincere good-will for all Americans now existing throughout Italy. It meant much to the Allies to have a visible sign that the United States was actively in the war and ready to devote every man and resource to winning the war. It meant much to Americans to realize that in Italy the United States had an ally whose great heart was open to Americans, ready and willing to cooperate with the latter zealously and effectively. There is scarcely a village where the American Red Cross has not brought a message of friendship to the Italians, who for three years have bravely borne the burden of history's most terrible war. During April representatives of the American Red Cross, traveling day and night, visited more than 2,000 towns and villages distributing relief among 318,200 needy families of soldiers at the front. The American Red Cross has now in operation throughout Italy 41 kitchens, distributing 120,163 rations weekly, 43 workrooms, employing 3,000 women, producing 63,800 garments monthly; 30 schools teaching 2,258 children; 10 hospitals for children who during the summer will be transferred to camps; 14 lace, mattress, shoe, and carpentry shops; 3 shops selling American dry food at nominal prices; 5 children's asylums, and 10 rest stations and canteens for soldiers and refugees, feeding thousands daily. It is hoped soon to build a model American village near Pisa housing 2,000 refugees. At the front the American Red Cross has four ambulance sections and seven rolling kitchens or canteens, giving tired soldiers hot coffee and jam.

At the opening of the session at a recent meeting of the Academy of Medicine, the president rose and called the attention of the academy to the fact that they had as guest Dr. Strong, the distinguished professor of Tropical Pathology of Harvard University, and that in the name of the Academy he desired to salute in him the magnificent work done by his country for the Cause of Humanity.

3. The Present Status of Immunization in Hay-Fever.—J. L. Goodale presents the results of an investigation begun in 1914 to determine the value of desensitization in hay-fever. The review includes 330 cases of true hay-fever, 123 of which had received desensitizing treatment for two or more years. The following were the results, based upon the statements of the patients and the author's own observations: (1) No improvement noted, 7 cases. (2) Improvement as compared with previous years, but showing, nevertheless, troublesome symptoms for a short time, 46 cases. These patients in general may be considered as only moderately well satisfied with the results, and, in my opinion, were not materially better than most cases treated in previous years by cauterization and general hygienic measures. (3) Very definite improvement, apparently beyond criticism, was observed in 59 cases. These include patients with a previous history of severe attacks, who, under treatment, exhibited only slight symptoms, causing not more than moderate annoyance. Here are included patients with a previous history of hay asthma, who were able to go through two or more summers without asthmatic symptoms. (4) Five patients showed no hay-fever for two or more years. By this is meant complete absence of subjective or objective vasomotor disturbance, in spite of full exposure to pollen.

5. Can Flat Foot Be Cured?—J. Madison Taylor answers this question in the affirmative, if the condition be properly treated. He disapproves of arch supports, but favors a hollow heel with an elevation just anterior to the calcaneum. This permits the os calcis to rest comfortably in its normal position, leaving the whole foot free to function normally, and holding it back from the compressing action of the front part of the shoe on the toes. The rigidity of the metatarsophalangeal joints must be overcome by persistent and skillful manipulation, bending the toes down till gradually the normal flexor action can be performed. At the same time the toes should be forcefully widened, *i.e.* separated and stretched apart, until with the foot resting on a step or raised surface the toes can be bent at an angle of 90 degrees, *i.e.* from the horizontal to the vertical. On standing on a step the toes should be made to touch the upright (vertical) surface below them. This facility, passive though it be, is only acquired after months of careful molding and mobilizing. At the same time the patient should make voluntary

efforts to perform flexion acts, *i.e.* to bend down or flex the toes as nearly as possible to an angle of 90 degrees. This movement is a normal but long lost flexor function. When flexion can be readily performed daily, the arch has become practically normal. Power will be increased by performance. There are in addition many other accessory movements of equal importance. Among these are placing the bare foot on the floor about 20 inches in advance and then pressing down with the toes, drawing the foot toward one at the same time rotating it inward, describing the quadrant of a circle. Of course this involves work, hard work, but the price of emancipation from any protracted motor disability is viligant and persistent correction of faulty action.

4. On Disappointments of Various Therapy. H. G. Adamson.

1. **The Lumleian Lecture on Cœliac Disease.**—G. F. Still devotes this first lecture to the symptoms and prognosis of this disease. A remarkable fact developed from his own series of cases was the greater frequency of the disease in girls than in boys, only 11 of his 41 cases being in boys. The child is pale and emaciated, the large abdomen contrasting with the wasted limbs. The stools are bulky, pale, porridge-like, and greasy; later, however, they become greenish or dark brown in color; the odor is very offensive. The urine is usually normal. The liver is not enlarged, and may even be smaller than normal. There is marked pallor, due to the deficiency in hemoglobin, which is the only constant blood change. One of the most striking features of the disease is the arrest of physical development, not merely a cessation of gain in weight but also in arrest of growth. The voice is high pitched and feeble, in contrast to the rather gruff voice in other conditions associated with arrest in growth such as cretinism. The dentition may be slightly but not markedly delayed. There is great muscular weakness. The mental capacity does not seem to be affected. Among the complications observed were general edema, tetany, scurvy, purpura, and chronic glossitis. The disease is very chronic in its course, and when recovery occurs it is not until the end of a year or two. Whether complete recovery, in the sense of attaining eventually average height and acquiring normal puberty development, ever occurs, the author cannot say from personal observation, but he has knowledge of two cases in which this was said to have occurred. Six cases of the forty-one ended fatally, two of them, however, from accidental complications.

4. **Blood Pressure in War Traumatism: a Possible Source of Error.**—Edgar F. Cyriax calls attention to a possible source of error in the reports of blood pressure in war traumatisms, in that he has found that in a certain proportion of unilateral traumatisms the pressures in the two arms may show wide differences. Not only is this so, but the readings on one day may be higher in one arm than in the other, but the reverse a day or two later. When differences occur they generally diminish as improvement proceeds and disappear some time before complete recovery. His readings were taken with Riva-Rocci apparatus, and were measured alternately first from the one arm and then from the other on successive days. The interval between the two readings on the same day varied from five seconds (two apparatuses being employed) to ten minutes. Neither the length of this interval nor the arm in which the pressure was first estimated seemed to have any influence on the actual readings; this was shown by a number of controls taken from ten to thirty minutes later. These were obtained first from the arm which was dealt with last and with a different interval. Thirty-six cases were examined in all; in twenty-six no difference, or only a slight difference (2 to 4 mm.), was found; such differences were considered negligible. In six cases differences of 6 to 8 mm. were found, which sank to about half this amount about three days later, and disappeared at the end of the week. In the four other cases, details of which are given in tabular form, the differences ran from 6 to 22 mm., and in two increased rather than diminished during the period of observation lasting about a month.

Münchener medizinische Wochenschrift.

June 25, 1918.

War Enuresis and Its Relation to the Elimination of Chlorides and Carbohydrates.—H. Rietschel tells us that nocturnal enuresis in adults has considerably increased during the war, particularly during the winters of 1916 and 1917. This enuresis is also met with in wounded soldiers, but is especially common among the civilian population. There is always polyuria, pollakuria, and nycturia. The writer insists on the latter symptom because it indicates that there is above all a delayed urinary elimination. This nocturnal polyuria occurs in neuroarthritic subjects and in those having a "weak bladder"; the enuresis would not arise if the conditions of emptying the bladder were normal. To explain the process, the writer bases his remarks on his knowledge of infantile pathology. The chlorides and hydrocarbons possess an hydropigenous action, delaying aqueous elimination, as has been shown by Volhard and von Hiemann. Since the food of the German population is now especially composed of potatoes and bread, both of which are rich in potash, a chloride retention results, which in itself has an hydropigenous action and this becomes added to the hydropigenous action of the carbohydrates. From this nycturia results, and when the enuresis arises it is due to a disturbance of the bladder reflexes. The writer remarks that this condition is both debilitating and humiliating to the German people.

Should Antityphoid Vaccination Be Done During an Epidemic of Typhoid Fever?—A. Hegar and W. Mockel state that this is a mooted question because according to many writers, during the period of formation of the antibodies and bacteriolysins the receptivity for

the bacillus is greater (negative phase of Wright). An epidemic of typhoid occurred in the insane hospital at Wiesloch and the writers vaccinated all the inmates and personnel (1500 persons in all). The percentage of rise in temperature above 101.5° F. was 2.5 — 2 — 1.5 per cent. for the first, second, and third injection respectively. One hundred and twenty-nine cases of typhoid occurred. The proportion of serious cases before vaccination was resorted to was 44 per cent. and 23 per cent. among vaccinated subjects. Eight subjects were vaccinated during the incubation of their typhoid, the disease running a normal course with, perhaps, a lower temperature than usual. No complications were observed and the epidemic was, in fact, nipped in the bud. Therefore the writers reply in the affirmative to the question they put forward.

Deutsche medizinische Wochenschrift.

June 20, 1918.

Experiments with Antityphus Vaccination.—Möllers and Wolff have employed a serum taken from the blood of patients with typhus fever. They noted a febrile reaction when the serum furnished by the German sanitary service was used, and this reaction they attribute to the fact that the product was infected. They therefore added 0.2 per cent. formalin to it to overcome this infection. Experiments on guinea-pigs with this serum gave very satisfactory results, although many of the animals died from anaphylactic shock. Six hundred and fifty vaccinations were done on human beings and 21 of these subjects contracted typhus as follows: Six persons who were vaccinated during the incubation period; four persons who received only two injections instead of three; six persons developed typhus more than three months following the vaccination, and five persons developed the disease in less than three months following the vaccination. Möllers and Wolff conclude that antityphus vaccination is not more dangerous than those for typhoid or cholera and that it does not confer any greater immunity than do the latter two, as they had five positive cases, one being fatal out of a total of 650 vaccinated subjects, the typhus in these cases occurring in less than three months following the vaccination.

Successful Results with Autoserotherapeutic Treatment of Typhus Fever.—Lazló Gyori employs the blood serum taken from the patient himself. The forty-one cases so treated may be divided into three groups as follows: (1) Cases in which the serum was removed on the eighth day of the disease. (2) Cases in which the serum was removed before the eighth day of the disease. (3) Children and young adults. In group 1 a rapid fall in temperature was noted, likewise an amelioration in the general condition which made cardiac stimulants and antipyretics unnecessary. In group 2 the results were less marked, while they were nil in group 3, but in children the disease is more serious than in adults. The writer believes that autoserotherapy in typhus is especially efficacious in serious cases, but should not be resorted to before the end of the first week of the disease, during which time balneotherapy is to be employed.

Deutsche medizinische Wochenschrift.

June 27, 1918.

A Prophylactic and Curative Serum for Weil's Disease.—Uhlenblutt and Fromme have, from their studies on Weil's disease, been led to manufacture a serum whose curative virtue they consider absolute. They have noted that the blood-serum of animals and man infected with the icterogenous spirochete contains antibodies which persist for seven months, two years and six months, or even twenty years after recovery from the disease. The writers' "hyperantitoxic artificial serum" is manufactured as follows: Cadavers of guinea-pigs infected with the spirochete are skinned and the digestive tract removed. The cadaver is then cut into small bits and reduced to a mush in the autoclave. The blood solution obtained from this mush is mixed with physiological salt solution in the proportion of 1 liter for each cadaver. This serum is injected into sheep and horses at the dose of 50 to 100 c.c. from time to time during two years, or 100 to 1000 c.c. during eight months. The serum of the animals thus treated possesses an antitoxic power of 1/100; 0.01 c.c. of this serum neutralizes 1 c.c. of virus. The serum has a distinct curative power when injected at the beginning of the disease, before icterus has appeared, if employed in the dose of 50 c.c. injected into the muscle or intravenously.

Pseudocerebellar Ataxia from Lesions of the Temporal Lobes.—Knapp shows that lesions of the temporal lobes may cause an ataxic syndrome absolutely simulating cerebellar ataxia. This ataxia is an important symptom of lesions of the temporal lobe, after which should be mentioned sensorial aphasia (left temporal lobe), partial paralysis of the third pair and contrololateral hemiparesis due to compression of the cerebral pedunculus. These four symptoms serve to differentiate pseudocerebellar temporal ataxia from true cerebellar ataxia, as there is nothing characteristic in the gait which would lead to a correct diagnosis. At autopsy, as Loewenstein has shown, there is no macroscopic nor microscopic lesion of the cerebellum. Pseudocerebellar ataxia from lesion of the temporal lobes is, consequently, not due to a distant action on or by extension to the cerebellum, corpora quadrigemina or the labyrinth, and should be considered as a focal phenomenon. It can only be explained by admitting that the temporal lobe is the center of equilibrium.

The Stages of Azotemia in Bright's Disease.—Widal, Weill and Pasteur Vallery-Radot contribute a characteristic article on their most recent conception of this subject. The statement is reiterated that in the 1 gram of urea per liter stage there is no chance for involution—death will almost always occur within two years. With less than 1 gram per liter the prognosis is not so inexorable. The authors have now been able to follow up old material over many years and have accumulated data on lower degrees of azotemia. If the amount per liter is between half a gram and a gram, the course of the disease may be of several types. The disease may recede altogether or may remain almost at a standstill. Exceptionally the figure may even exceed 1 gram per liter. In one case in a young man under treatment since 1913 the urea has oscillated between 0.62 and 0.98 grams per liter. His condition is now excellent, edema originally present has long vanished, and the only symptoms of the disease are albuminuria and cylindruria. Such a case shows that one must be careful in prognosis in a case so near the 1-gram mark. The stage of half a gram to a gram of urea per liter represents the first stage of accumulation, but not the first stage of abnormal excretion. Ambard's coefficient shows us in advance of this period when there are disturbances in N excretion. An increase in the coefficient is often seen in nephritis when the blood urea is normal. The authors have also seen a normal coefficient in 17 nephritics who had less than half a gram of blood urea per liter. An increase in the coefficient is so common in Bright's disease without azotemia (76 per cent.) that it may be regarded as a symptom of that affection. In a large number of cases the increase is only transitory, but even when the increase is permanent it does not mean azotemia. In one patient followed up for eight months the coefficient was increased throughout, but the blood urea kept within normal limits. Two years later his blood urea was above 1 gram per liter and four years after the first analysis death occurred. In two other cases the outcome was of the same character after years of latency. In a fourth case in which blood urea was less than 1 gram per liter Ambard's coefficient did not permit a prognosis of the duration of the disease. The relation between the coefficient and azotemia is merely this: that with a lessened amount of renal parenchyma there may still be no pathological retention of nitrogen. When the azotemia exceeds the 1-gram mark it is useless to determine the coefficient. To sum up, a permanently increased coefficient may be conceived as a period of pre-azotemia. When azotemia between 0.5 and 1.0 gram has appeared we have the second stage

of ureosecretory trouble and the first stage of urea accumulation. When the 1-gram mark is surpassed we have the third or fatal phase, when we can foretell the outcome with considerable certainty.

February, 1918.

Fever with Sarcoma.—Schiotz reports a case in a woman of twenty-five who late in April, 1917, began to complain of pain in the side with loss of appetite and strength. Later she developed an eruption and diarrhea. She was first seen May 15 with temperature 104, pulse 140, blood pressure 75. The exanthem paled out in a few days, during which she had a series of chills, one each day. She seemed to be septic and on the 25th was given intravenous injections of collargol. No intra vitam diagnosis seems to have been made, and the objective finds were few, slight and equivocal. Section showed a general sarcomatosis of most of the lymphnodes, sarcomatous deposits in the pericranium and dura, sarcomatous ulcers of the tonsil and stomach and degeneration of most of the viscera. Death had occurred from marasmus. The dominant symptom in this case had been the fever of a pseudo intermittent type. Every other symptom was insignificant. The case should be called "sarcoma fever." Several such are on record.

Renal Function in Prostatics.—Bie states that the late Paul M. Pilcher was the pioneer in this study. At the time of his death the late Ojestland was working along these lines. The author continues his labors. The tests were as follows: Diuresis; solids excreted daily; specific gravity; phenolsulphonephthalein test; urinary constituents in blood stream. The author relates 12 cases in detail, but does not draw very full or final conclusions from them. All show evidences of overburdening and back pressure on the kidneys. The tests have little prognostic value, for even with notable urea retention for prostatics there was good survival and health, and the same is seen with poor elimination as shown by the phthalein test. One man is living and vigorous after 30 months with thalein 30 per cent. and blood nitrogen 1.46.

Brazil-Medico.

Sporotrichosis in Brazil.—De Rezende relates the case of a woman in the poorhouse of Guaratingueta who was referred to the hospital for what were alleged to be two wounds of the left hand. These were seen to be productive lesions, very hard and prominent, adherent to the subjacent parts and surrounded by reddened skin. Both lesions showed superficial ulceration and an adherent fibrinous deposit. A month before the lesions had begun as what were judged to be mosquito bites and had increased steadily in size. There was no reaction in the lymphatics. The latter fact at once excluded primary syphilomata, which lesions were strongly suggested. An injection of an organic arsenical compound was made into the muscles. Forty-eight hours later distinct improvement was apparent and the injection was repeated, but no further benefit was noted and syphilis was definitely excluded. The lesions then proved resistant to the local exhibition of antiseptics. An expert diagnostician who was called in counsel placed the patient upon mercury, iodide of potassium and sarsaparilla, and the lesions gradually disappeared. During the following year the author saw very similar lesions on the face of a boy aged 11 years. These were seated respectively on the bridge of the nose, middle of forehead and temporal region. Others appeared in the submaxillary region and left forearm. The affection dated back five months. A distinguished physician had been unable to make a diagnosis. There was not and had not been the least reaction in the lymphatic system. All of the lesions were ulcerated and none showed any tendency to cicatrize. The patient received intensive local and general treatment in vain —Donovan's solution and local caustic applications—when as a last resort a simple dressing of sublimate, 1 to 1000, effected a rapid cure. In speculating on the nature of the mysterious affection a diagnosis by exclusion of sporotrichosis was made. Cases of the latter were known to occur in Sao Paulo in the same province. At this juncture two other cases appeared in the city and yielded promptly to sublimate, 2 to 1000, locally with potassium iodide inwardly. The author apparently had no laboratory facilities and was aided in his diagnosis largely by a comparison of his photographs with those of cases published in which cultural researches were positive. The recovery under potassium iodide is evidence of this affection.

Hospitalstidende.

April 17, 1918.

Treatment of Night Blindness with Liver Substance.—Von Stenitzer and Schroeder, because of a multiple experience that individuals who ate liver daily escaped night blindness when it attacked a given community, decided to use cooked liver in the treatment of that affection. That this idea is not new well appears in a discussion on night blindness which appeared in the Hospitalstidende in 1904, where it was stated, in connection with hemeralopia in vagabonds, that this condition disappeared after the daily consumption for three successive days of half a pound of calf's liver. Ronne, the ophthalmologist, has recently made a similar observation, but is sceptical in regard to any possible specific activity of liver substance, choosing to ascribe the benefit solely to the nutritive value of the organ. The authors subjected thirty-four patients with hemeralopia to exclusive liver treatment, 200 grams of steamed liver being fed them daily. Of this number thirty made complete recoveries and the other four were benefited. The duration of treatment varied from six to seventy-eight days. Most of the patients gained weight, from a fraction of a kilo to over 11 kilos. But at the same time twenty-four controls with night blindness received no treatment at all, yet twenty recovered completely and three were improved. All controls also gained weight. A careful analysis of the two sets of figures shows absolutely nothing in favor of the liver treatment. Hemeralopia follows fasting and abstinence periods and disappears upon an adequate diet.

May 1, 1918.

Case of Narcolepsy.—Askgaard first cites ten observations from literature from Westphal's case of 1877 to the cases of Henneberg and Mendel published 1916. His own patient was a girl of fourteen of sound stock and not herself subject to any nervous disorder. The first of her attacks had come on four years previous without apparent motivation. Epilepsy could be excluded, but patient had been taking bromides and adonis for a long time without any benefit. When first examined she was seen to be finely developed for her years and free from any serious trouble. The case was followed up. Every few days she had brief seizures of somnolence, waking quickly. Some of the attacks occurred when she was busy with duties. It was impossible to study her during the paroxysms, for she always quickly wakened. She received no benefit from treatment. The case was evidently an independent neurosis.

A Toothbrush in the Stomach.—The following case published in the *Journal de Médecine et de Chirurgie Pratiques* for May 10 is believed to be unique. It was originally reported by Durand in the *Lyon Médical*. The victim was a woman with melancholia and ideas of persecution which tended to motivate suicide. It was doubtless with suicidal intent that she swallowed her toothbrush. The handle slipped down the gullet, the brush end pointing upwards, and entered the stomach. The *x*-ray revealed the latter fact and by reason of the emaciation of the subject the handle could also be felt through the abdominal wall. Gastrotomy showed that the brush proper had remained within the limits of the esophagus, having doubtless been arrested by the contact of the bristles. Had the object been smooth—a teaspoon, for example—it could have been expelled readily by the bowel. Durand had a patient who swallowed the same spoon twice.

Book Reviews.

Burns and Their Treatment: Including Dermatitis from High Explosives. By J. M. H. MacLeod, M.A., M.D., F.R.C.P., Physician for Diseases of the Skin, Charing Cross Hospital, Royal Flying Corps Hospitals, etc. Price, $2 net. New York: Oxford University Press, American Branch, 1918.

This book is dedicated by the author to "Our heroic airmen who, in spite of crashes and burns, still carry on." This was doubtless suggested by the fact that the author has had an extensive experience in the treatment of burns of all sorts at the hospitals of the Royal Flying Corps, as well as at the Charing Cross Hospital. MacLeod has written a very valuable little book for both the general practitioner and the surgeon in civil practice, as well as for those engaged in war work; while the added chapters on burns from corrosives and high explosives make it of particular value to present and prospective members of the Medical Reserve Corps.

Five chapters are devoted to burns from heat. In these, Dupuytren's classification into six degrees is described and much space is given to the discussion of symptoms, histological changes, prognosis, general and the various forms of local treatment, including the newer methods, as applied to the various degrees of burns. There are also chapters on burns from electricity, from lightning, from *x*-rays, from radium, from the sun, from corrosives, and from high explosives. All these subjects are well handled and the book presents a mine of useful information. While essential facts and descriptions of technique are given in few words, the author has the happy faculty of putting what he has to say in an interesting way; so that, without conscious effort, the reader gains the knowledge which the author wishes to impart. The book is thoroughly up to date and one cannot fail to feel well repaid for the time spent in its study.

Scopolamine-Morphine Semi-Narcosis During Labor By William Osborne Greenwood, M.D. (Leeds), B.S. (Lond.). Price, $2. New York: The Oxford University Press, American Branch, 1918.

This volume is written for the profession. Aside from the earliest results in Germany, the material appears to be taken essentially from the experience of British accoucheurs. The author's personal experience is in part neatly tabulated at the end of the book. He states candidly that numerous points are still to be elucidated. Chapters are devoted to technique, effects on the mother, effects on the infant and results. The total number of cases of labor was 200, without maternal mortality. The four deaths from still birth—2 per cent.—are a little less than the average of general midwifery practice. We see no summary as to the amnesia obtained, but there was a remarkable absence of shock and exhaustion.

The Treatment of Cavernous and Plexiform Angiomata by the Injection of Boiling Water (Wyeth Method). By Francis Reder, M.D., F.A.C.S., Visiting Physician to City Hospital, Consulting Surgeon to St. John's Hospital and Missouri Baptist Sanitarium, St. Louis. Price, $1.50. St. Louis: C. V. Mosby Company, 1918.

This little work contains an autographed introduction by Dr. Wyeth. There are sixteen photographs of separate patients treated and two colored plates, one of which is the frontispiece. There are other photographs of some of the patients after successful operation. The volume is of the rare type which every surgeon will buy on sight. The cost is negligible and the means are supplied for eradicating a most burdensome condition without risk of mortality and damage suits.

How to Enlighten Our Children. A Book for Parents. By Mary Scharlieb, M.D., M.S. Price, $1. New York: Fleming H. Revell Company, 1918.

This volume contains nine chapters which comprise discussions of the physiology and hygiene of puberty and adolescence, the social evil, venereal disease, eugenics, and allied topics. One chapter is devoted to the exegesis, so to speak, which may be used by parents to make these subjects intelligible to children. The book answers its purpose well and any criticism naturally applies rather to the type of volume rather than to the individual effort. It has not yet been proved that enlightenment brings results, but it is very difficult to understand how such a book could possibly do harm; hence we must give it the benefit of the doubt.

Treatise on Applied Analytical Chemistry. Methods and Standards for the Chemical Analysis of the Principal Industrial and Food Products. By Professor Vittorio Villavecchia, Director of the Chemical Laboratories of the Italian Customs, with the collaboration of G. Fabris, G. Rossi, R. Belasio, A. Bianchi, G. Silvestri, F. Barboni, G. Armani, G. Bosco, A. Capelli. Translated by Thomas H. Pope, B.Sc., A.C.G.I., F.I.C., University of Birmingham. Vol. I, with 58 Illustrations in the text. Price, $6.00 net. Philadelphia: P. Blakiston's Son & Co., 1918.

Although there is no lack of books on technical analysis, the present volume is of interest because it gives the standard methods adopted in Italy; and the very wide experience of the author and his collaborators gives unusual value to the methods here presented. As a rule only one or two methods are given for each test, but these are carefully selected as tests which have been officially prescribed or have been employed almost daily by well known specialists. In addition to these well selected tests the book contains numerous tables which show the average results of the analysis of different samples. The present volume deals with potable waters, chemical products, fertilizers, cement materials, metals and alloys, fuel, coal-tar and its products, mineral oils and their derivatives, fatty substances and the industrial products derived therefrom. A valuable feature of the work is the inclusion of various criteria and standards by the aid of which the industrial, commercial and hygienic value of various products may be ascertained from the analytical data which have been obtained. The book is well printed, and is so bound that it lies open at any desired page. It will prove a valuable addition to the library of any laboratory in which industrial or food analysis is carried on.

Chemistry of Food and Nutrition. By Henry C. Sherman, Ph.D., Professor in Columbia University. Second Edition, Revised and Enlarged. Price, $2. New York: The Macmillan Company, 1918.

The first edition of this work appeared in 1911 and contained 355 pages. The present edition, with about one hundred additional pages, is issued at the old price—$2—a remarkable value for the buyer. The table of contents shows that it is virtually a new book. Hardly any of the chapters of the first edition are recognizable in those of the second. The number of indexed titles has nearly doubled. The book runs to real facts and there is no reason for the contrary, although most books still incline to the dogmatic and speculative. But there are not so many facts as there should be; for example, we do not find a table of the magnesium content of the leading foodstuffs, although the author might have supplied one.

The Surgical Clinics of Chicago. Volume II, Number 2, April, 1918. Octavo of 209 pages with 80 illustrations. Published bi-monthly. Price per year, $10. Philadelphia and London: W. B. Saunders Co., 1918.

There are nineteen contributors to this number, and a wide range of subjects is discussed. One of the most interesting articles, even if it is not of great value from the standpoint of clinical teaching, is that by Roy L. Moodie, Ph.D., entitled "Pathologic Lesions Among Extinct Animals; A Study of the Evidence of Disease Millions of Years Ago." Among the lesions mentioned, and in some cases illustrated, are necrosis and exostoses of bone, various examples of arthritis, hemangioma in the tail of a dinosaur 18,000,000 years old, and a photomicrograph showing bacteria supposed to be 100,000,000 years old. The author finds no geologic evidence of syphilis prior to 500,000 years ago. Among other articles of more value to the practitioner of to-day are that of Ochsner on gallstones, Bevan's article on salivary calculi, Oliver's presentation of several cases of sarcoma, and Mitchell's article on the extra-genital chancre as a complication in minor surgery.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting Held January 10, 1918.

DR. HERBERT B. WILCON IN THE CHAIR.

Acute Infectious Jaundice in Six Children in One Family.—Dr. CHARLES HERRMAN presented this communication, in which he said that two cases of acute infectious jaundice in one family were not uncommon, but he had been able to find only one other instance of six cases in one family, namely, that reported by Rankin in 1894. In the family under consideration there were nine children. The eldest two, boys of 18 and 16 years respectively, were not affected, probably because they went to work early in the morning and returned home late, so that they did not come in contact with the younger children. The remaining children ranged in age from twelve to two years. All contracted the disease between October 1 and November 3. An infant six months of age was not infected. The rarity of catarrhal jaundice in young children was probably due to their relative natural immunity which they enjoyed from other infectious diseases. The disease in the six children followed its usual course, beginning rather suddenly with headache, drowsiness, and lassitude, rise in temperature, and, in some instances, by vomiting at the onset. After three or four days the conjunctiva became yellow, the urine dark, the stools light in color. At this time examination of the patient showed a distinct enlargement of the liver, some enlargement of the spleen, pain in the epigastrium, and some pain in the legs. In ten days the urine and stools regained their normal color; the pigmentation of the conjunctiva and the enlargement of the liver persisted for a somewhat longer time. In two of the children, after ten days, there was a secondary rise in temperature which lasted for a few days. An infectious jaundice was epidemic in New York every few years, the last epidemic occurring in the latter part of 1912 and the first part of 1913, when the writer reported 98 cases which he had seen during the previous six years. The disease might present itself in all grades of severity. The infectious material apparently had a special affinity for the biliary passages in the same sense that the typhoid bacillus had for the follicular structures of the intestinal tract. Indiscretions in diet played no part in the etiology of the disease. The seasonal incidence and the frequent presence of catarrhal symptoms in the upper respiratory tract would point to the nasopharynx as the possible portal of entry of the infectious material. During the present epidemic the writer had seen 15 cases in addition to the ones herein reported, all in the borough of the Bronx. The course of the disease was in all respects similar to that observed in other groups. The fact that six cases occurred in one family and that two cases occurred in each of two other families occupying adjoining apartments tended to indicate that the disease was mildly communicable. Epidemics of acute infectious jaundice had frequently occurred in camps. During the Civil War there were 23,500 cases with 161 deaths. Large numbers of cases had occurred in the Franco-Prussian and Boer wars and in the camps of the French and British during the present war. About three years ago several Japanese investigators succeeded in finding a specific spirochete, which was present in acute infectious jaundice. To this disease they gave the name of "Spirochetosis icterohemorrhagica." This name was appropriate in the severe cases, but there was a certain percentage of cases without jaundice and without hemorrhagic tendency. The spirochete was found in the circulating blood only during the first few days of the disease and then only with the greatest difficulty. If the blood taken in the early stage was injected into guinea pigs intraperitoneally, they developed the characteristic symptoms of the disease in from four to five days and died a few days later. The spirochetes could be recovered from the blood and from the liver and in smaller numbers from the kidneys and suprarenal capsules. A few might be found in the spleen, bone marrow, and the lymph nodes. In acute infectious jaundice of this type the spirochete might be found in the urine during the third week, also in the stools, and occasionally in the sputum. In patients and inoculated animals, in which the disease was produced, the serum after the second week contained immunizing substances. If this convalescent serum was injected into guinea pigs which had been inoculated before the appearance of the jaundice, the disease did not develop and the spirochetes disappeared from the blood shortly after the introduction of the serum. The type of infective jaundice seen in New York was mild and except for this fact varied in no way clinically from that described by Japanese, French, German, and English observers. The English observers gave a mortality of four to five per cent., while the Japanese gave a mortality as high as 32 per cent. For this reason it seemed not unlikely that the disease as it was observed here bore the same relation to spirochetosis icterohemorrhagica that so-called Brill's disease did to typhus fever. The absolute proof of this relation would, of course, depend upon the finding of the specific spirochete in the cases seen here.

Dr. HENRY KOPLIK called attention to an epidemic of acute infectious jaundice recorded by Dr. West which had escaped the observation of the writer of the paper, and recalled an instance in which two children in an Italian family were affected by the disease. He cited another instance in which three children in one family were infected. Some were inclined to attribute the severe cases, with marked jaundice, gastrointestinal symptoms, hemorrhagic tendency, and enlarged spleen, and the mild cases to the same organism, but he thought the better way to look at it was that the different types of the disease were caused by different types of organism; some might cause the severe cases, the so-called Weil's disease, and another type of organism might cause the cases of mild infectious type.

Dr. CHARLES GILMORE KERLEY added another instance of several cases of acute infectious jaundice occurring in one family. In this instance the mother and four children all had the disease at the same time. None of them was particularly ill; they had some fever, catarrhal symptoms, and jaundice, and all made good recoveries. It was of interest in connection with this family that they lived in a malarial section and they had all had malaria during the previous summer; they then came down in the fall with the acute infectious jaundice of rather mild type. This had been a rather unusual experience with him, but he supposed the cases came under acute infectious jaundice.

The Hypertonic Infant; the Curative Action of Atropine on Certain of Its Manifestations.—Dr. SIDNEY V. HAAS read this paper, in which he described the hypertonic infant of a definite clinical type, characterized by hypertonicity of all the skeletal muscles. He stated that the hollow viscera showed increased activity of their smooth muscle fibers, which expressed itself in the form of spasm involving practically every part of the digestive tract and, depending upon the region, presented the symptoms of colic, visible peristalsis, vomiting, constipation, or any combination of these. The hypertonic infant presented the symptoms of vagatonia. Food regulation alone did not correct the fault, whereas treatment by the drug atropine was followed by a rapid subsidence of the symptoms, the result being so prompt and regular as to constitute a specific action. The tolerance for milk, which was usually low in these infants, was at once materially increased so that a normal amount might be utilized. In the teaching of infant feeding both the food and the infant had been studied from many angles, but few serious attempts had been made to study the possibility of altering the infant's reaction toward food when it was found impossible to adapt the food to the infant. Personal experience during the past few years had convinced the writer that in this direction lay a field which was full of promise. To make clear the course of reasoning that led to this conclusion, Dr. Haas reviewed some points in reference to the vegetative nervous system, stating that that vegetative nervous system was divided into two parts, the sympathetic and the autonomic. The sympathetic reacted to small amounts of adrenalin. The autonomic nervous system was all that portion not included in the sympathetic, including the vagus, and reacted to very small amounts of acetylcholine.

Under normal conditions these two systems, sympathetic and autonomic, were in equilibrium, producing a tonic innervation of smooth muscles. Stimulation of one or the other of the two systems by hormones or other factors might produce spasm, contraction, or paralysis. For instance, vagal stimulation might cause turbulent gastric peristalsis and might manifest itself in vomiting. Hence the benefit upon cardiospasm of atropine. Owing to the close relation of the glands of internal secretion, the autonomic nervous system doubtless had a marked influence not only upon the pancreas and the thyroid glands, but also upon the entire mechanism of metabolism. The essayist stated that there were a number of apparently healthy, normal infants fed upon the breast who took their food with satisfaction, grew, and increased in weight, but were unhappy and restless, cried more or less constantly, and slept only at intervals for short periods of time, vomited, and were constipated. A much larger number of artificially fed infants reacted in this abnormal manner and presented this same picture. The cause of this state was to be found in the manner in which the individual child reacted to its food. In this group were to be found the colicky baby, the irritable baby, the sleepless baby, the restless baby, the baby which did not prosper on any food, although there was neither gastric nor intestinal indigestion, the baby suffering from pylorospasm accompanied by vomiting, usually projectile in type, and the constipated baby. Without exception these infants were of the spasmophylic diatheses and usually had a neurotic ancestry. The usual therapeutic procedures and rearrangement of the diet were as a rule insufficient to relieve the symptoms. The vomiting was not related to the taking of food, but was characterized by its irregularity. These cases passed from hand to hand, changes were made in the formulas and method of feeding, but usually without much result. The correct therapy in these cases showed results which were remarkable in their regularity and with the rapidity with which they occurred. In cases in which indigestion existed, this, of course, must be improved by appropriate methods of feeding; as a rule, however, no change in the diet was necessary. By the administration of atropine in sufficient doses, the entire picture changed in from forty-eight to seventy-two hours. The atropine was administered in 1-1000 solution, beginning with one drop in each bottle and increasing it, in forty-eight hours if there was no improvement, to two drops in each bottle, and later to three or four drops if necessary. An interval of forty-eight hours was allowed between changes in dosage. If the diagnosis was correct the atropine would control the frequency of the vomiting, the child would begin to sleep much better and for longer periods, and was more comfortable in its waking moments. There had been no ill effects noted from these large doses of atropine in infants. If atropine were used early and in sufficient dosage the number of cases of pylorospasm which finally reached the operating table as cases of hypertrophic pyloric stenosis would be reduced to an unimportant minimum. It was not to be supposed that all infants who vomited, cried, were constipated, or sleepless, would respond to this treatment. If the cause were anywhere else than in the autonomic nervous system there would be no result from this treatment. The earliest effects of atropine in infants was a flushing, which gave them the appearance of having fever (this sometimes existed but usually was not high), dilatation of the pupils, and slight puffiness of the eyelids. A series of typical cases belonging to the group of hypertonic infants was reported in detail in which atropine relieved the condition immediately and apparently increased the infant's tolerance for milk.

Dr. Charles Gilmore Kerley said he was hardly prepared to discuss the use of atropine in this class of cases, as he had never employed this measure for the class of cases Dr. Haas described. Dr. Kerley asked Dr. Haas how he diagnosed pylorospasm and whether he had any cases that might have been diagnosed as pylorospasm and later turned out to be pyloric stenosis. It seemed that in this series of cases all recovered. One could take up a series of cases and use a familiar line of treatment and all of the cases would get well by some fortunate chance; it was always an advantage in reports to include those that did not get well. This presentation, however, seemed to supply a means of apparent value of treating difficult feeding cases.

Dr. Koplik said he was struck by the fact brought out in the paper that pylorospasm and pyloric stenosis might be relieved by atropine or by other methods of treatment. There were some cases of pyloric stenosis and spasm absolutely cured by a variety of drugs and by a variety of lines of treatment, if one could persist in the treatment until the child improved, but there were cases in which operation was indicated, and which he doubted if anything but operation would help, and in which at operation much thickening of the pylorus was found, indicating that nothing but an operation would have been effective. It was difficult to see how anatomical stenosis of the pylorus could be relieved by atropine. There were cases in which the treatment brought forward should be used, but in some cases we would not get the action of atropine so brilliantly as had been pointed out this evening. He had never used it and did not think we would find it a *sine quo non* in cases in which the metabolism and physiological functions were disturbed. That was the idea he wished to combat. We should be careful not to think that we had one drug that would gloss over many cases, and he should feel very sorry to see sidetracked those well-known principles of feeding which were applied in feeding children whom formerly we could not help on account of lack of intimate knowledge of the fundamental principles of infant feeding.

Dr. Godfrey R. Pisek said they all recognized that Dr. Haas had been treating a type of infants in which attempts had been made to adapt them to many different formulæ. The child cried, vomited, had increased peristalsis, and all the train of symptoms that had been described as a result of the many types of feeding that had been forced upon it. If one took a series the same type as these and adjusted the feeding in the way he had been accustomed to doing he would get the same kind of a chart that had been shown tonight. It would be unfortunate if there should go forth from the meeting tonight a note to the effect that feeding was not so important and that by giving atropine these children might be carried along with a certain measure of success. Certain children reacted very badly to atropine. If the drug were generally used to control vomiting, there would be great danger that it might come to be used in dispensary practice and that the dosage might be increased above the limit of safety.

Dr. Herman Schwartz said it was not an uncommon occurrence that babies that were vomiting a great deal were not retaining enough food to nourish them properly, and he noticed that in most of the babies in this series Dr. Haas increased the amount of food, giving them about what a normal baby would have. Although the babies were hypertonic babies a great deal of their crying and restlessness was due to hunger. The different doctors who had treated them had reduced the amount of food they were getting and when Dr. Haas came along he increased it to the proper amount. The child might continue to vomit, but as it had taken more food, more would remain in the stomach, and as a result the child would gain in weight. If he had only given atropine and made no change in the food he would have proven something more definite.

Dr. Thomas Southworth stated that he had used atropine and had found it a distinct adjuvant in cases of vomiting. It was also true that he prided himself that the good results obtained were partly due to manipulation and adjustment of the diet to what he considered proper feeding. Nevertheless it did seem to him that we did have a certain amount of irritation and spasm of the pylorus in which the atropine might be a definite aid. He thought the reason there had been criticism was that in making his presentation Dr. Haas had appeared to lay stress on the weight curve of the charts, whereas he clearly stated that a cessation of vomiting, irritability, and constipation was more éclatant than the mere gain in weight.

Dr. Ward B. Hoag related an experience that he had had with atropine in an infant of the type described by Dr. Haas. In this case, without making any change in the formula but simply adding the atropine, the baby was brought to fairly good condition and the vomiting ceased. He could not attribute the marked change in this baby to anything but the atropine.

Dr. CHARLES HERRMAN said that in a large percentage of cases of pylorospasm the infants were at the breast. A certain number of these were rapidly improved by the administration of atropine without any change in the feeding, so that the decrease in the amount of vomiting might be ascribed solely to the use of atropine. Dr. Haas surely did not mean that atropine was to be used in all difficult cases of feeding, but only in a certain group of cases that represented a definite clinical entity. Not all of these, however, reacted favorably to atropine.

Dr. HAAS, in closing, explained that it was not intended that atropine was to be used in difficult feeding cases; it was absolutely of no use unless the case belonged to this group of hypertonic infants. From his study it seemed that the condition was dependent upon the vegetative nervous system. He thought that if those who were skeptical would try atropine in cases of irritability and vomiting, they would find that it would cure some of these cases. After experience with several of these cases one recognized them at once and would know that they belonged to the hypertonic group. Dr. Hoag had answered Dr. Schwartz's question very well, but if further proof were needed that the food was not responsible for the good results it was found in this: After giving atropine for a time, an attempt was made to stop it. In some cases the child got along without it, but this was not always the case; in almost every case repeated attempts were made during the course of months to stop it, but with immediate recurrence of symptoms, until a time arrived when apparently the drug was unnecessary. Of course in the use of atropine it was essential that care should be taken. Eppinger and Hess believed that the reason better results were not obtained from the use of atropine was because of insufficient dosage. They had been giving 1/10 of a grain a day, without the deleterious effects that had been spoken of. In a very large number of cases in which he had used this drug on infants only two cases which he had cited gave any severe symptoms. He did not mean to say that atropine was the only drug that would do the things described. He believed that after investigation it would be shown that there were several drugs which would have an effect, not only in this group but in other groups as well. Dr. Haas referred to several cases in which operation was advised for pylorospasm which were relieved by atropine. He said he had no opportunity to use this drug in true pyloric stenosis, but unless the case was in good condition, where a delay of several days in operating was unimportant, its use would be unjustifiable, in view of the excellent operative results. The way in which he had sifted out the cases belonging to this group was if there was no improvement after the administration of atropine, he concluded that they did not belong to this group, such as cases in which there was just vomiting or just constipation.

Obscure Foreign Bodies in the Bronchi and Esophagus.—Dr. SIDNEY YANKHAUER made this presentation, the purpose of which he said was to call attention to the fact that a foreign body might be present in the bronchus of a patient who had no recollection of and who denied the history of its inhalation, in whom the radiograph showed no shadow which could be interpreted as a foreign body, and in whom the physical signs and clinical symptoms closely simulated other diseases. It did not always happen that every suspicion of a foreign body was absent, but it was worth while to remember that there might be no clue that would lead to the diagnosis of a foreign body, and that a justifiable suspicion was an evidence of the highest clinical acuity. The classical symptoms for the diagnosis of a foreign body were: (1) The history of the inhalation or the swallowing of the object. (2) The physical signs, clinical course, and symptoms. (3) The radiographic picture. (4) Bronchoscopic examination. In the absence of history of the inhalation or the swallowing of a foreign body the object might be discovered by radiograph, but only if the foreign body were one which threw a distinct shadow on the plate. Bones small enough to be inhaled or swallowed, especially if they had been cooked and much of the mineral matter removed, did not throw distinct shadows. Chicken bones rarely threw any shadow at all, and likewise the bones of fishes, the kernels of nuts, the seeds of soft shells, were not usually recognized in the radiograph. But when the radiograph did not show the presence of a foreign body it was useful still in the diagnosis. For instance, in a boy five years of age, with the physical signs and clinical symptoms of a persistent consolidation of the left lower lobe in whom pus was withdrawn and a diagnosis of empyema made, the radiograph showed a shadow which was consolidated at the hilus, but toward the periphery of the chest clear lung tissue was found as far as the diaphragm. The diagnosis of probable lung abscess was made. Bronchoscopy was done as a matter of routine and also because of knowledge gained by experience, that these cases in children were frequently caused by the presence of a foreign body. Two pieces of peanut kernel were removed from the bronchus, and the dilated cavities were subsequently irrigated with physiological saline solution, with apparent recovery, though the case was still under treatment. On the other hand, the history might be absent and the foreign body of such a nature that it did not throw a radiographic shadow, and then the diagnosis might be made by the course of the disease and the physical signs. The auscultatory signs caused by a foreign body varied with the size and shape of the foreign body, with the degree of fixation in the bronchus, and with the amount of obstruction which it caused. A foreign body might be loose in the trachea and with each respiration might be shuttled back and forth. The irritation caused by such a foreign body would, of course, cause bronchitis. If the foreign body were practically fixed anywhere in the bronchial tree, so that it would move with the respiratory air current, sound would be produced which had been likened to the vibration of a Jew's-harp. If, on the other hand, the body were immovably impacted, the physical signs would depend on the amount of obstruction. It had happened that a patient had retained a foreign body in a bronchus for a long time, but such cases were rare. As a rule the presence of a foreign body set up a profound reaction. It was important for the physician to recognize the tracheitis which occurred shortly after the inhalation of a foreign body, especially in children. This tracheitis might be limited to the subglottic region, or it might extend down as far as the bifurcation. The secretion which was formed on the surface of the edematous mucous membrane was thick and tenaceous, causing considerable respiratory obstruction, sometimes sufficient to cause death. This tracheal edema might be recognized by a peculiar stridulous breathing which was heard in both inspiration and expiration, and which differed from the stridulous breathing of croup by the fact that the voice of the child had a clear and distinct tone even though the edema might be marked enough to cause considerable dyspnea. It rarely occurred that a foreign body was present in the bronchus and was not disclosed by the bronchoscopic examination in the hands of an expert. Failure to find the object with the bronchoscope would occur only when the body was so small that it had penetrated into a branch too small to be penetrated by the bronchoscope. It was usually possible to recognize and look into bronchi of the fourth order, but the interior of these small branches could be seen only in those branches which could be brought in line with the bronchoscope. Foreign bodies which had been present for a long time and had become encysted might also be beyond bronchoscopic visability. In closing, the essayist spoke of prophylaxis and suggested that others should be taught that nothing small enough to be swallowed should be placed in a child's hands, that objects easily broken, the pieces of which might be swallowed, should be kept from children, that pieces of instruments, such as sprays, syringes, etc., used upon children by parents, nurses, and physicians should have no loose parts or breakable ends, and that children and adults should be warned against holding objects of any kind in the mouth. Children should also be taught to permit the use of the tongue depresser, to allow their throats to be examined without struggle; this would permit a more frequent and a more thorough examination of the child's throat.

Direct Laryngoscopy in One Hundred and Eighty-nine Cases of Croup.—Dr. ROBERT W. GOVER read this paper, the report being based upon the records of cases of croup examined at the Willard Parker Hospital. There were 112 membrane cases in 36 of which intu-

bation was subsequently performed, there being but one intubation among the 77 cases showing no membrane. The advantages claimed for direct laryngoscopy in croup were: (1) In deciding as to the administration of antitoxin in a case of croup presenting no membrane in the fauces. (2) In deciding as to the necessity of establishing quarantine, or immunizing, or of testing the contents by the Solnick method. (3) In avoiding mistaking a foreign body in the larynx for croup. (4) In deciding as to the necessity for intubation. (5) In occasionally facilitating the removal of large pieces of loose membrane, with permanent relief.

Dr. Henry Lowndes Lynah expressed the opinion that Dr. Yankhauer was right in placing importance on the history. He related several instances in which cases of suspected laryngeal diphtheria were found on direct laryngoscopic examination to have a foreign body present, in one instance a safety-pin, in another a piece of meat, and in a third a mass of orange pulp. He also related an instance in which a child was supposed to have swallowed a button and the *x*-ray showed a shadow that appeared to be a button; the object in this instance was found to be a mass of casein. So far as the bronchiectasic bronchitis was concerned, when this was caused by the presence of a foreign body there was a peculiar inspiratory and expiratory dyspnea, a definite wheeze like that of an old asthmatic. If the membrane were slightly loosened it might act like a valve, blocking the expiratory air, which would then back up, balloon the lung, and compress the heart. He believed that Dr. Yankhauer was correct when he said that many cases in which a foreign body was present were interpreted as pneumonia or bronchopneumonia when if they had been studied more carefully it would have been found that the patient was suffering from having inhaled a foreign body. The points brought out this evening should be taken into consideration; we must always listen to the history of the case first and to the breathing next. Since it was now possible to wash out a lung abscess cavity this condition was not as serious as it formerly was since many of these cases by constant washing could be cured. Dr. Lynah said a matter that had impressed him was the danger attendant upon the efforts of parents and friends to remove a foreign body from a child's bronchus or esophagus. He cited an instance in which a child's tonsil had been completely enucleated by a parent trying to remove a pin from a child's throat. He thought Dr. Gover had demonstrated that direct laryngoscopy was a thing all physicians should do, both the pediatrician and the general practitioner, if called to see a case suffering from dyspnea for which there seemed to be no definite cause. Direct laryngoscopy did no harm if one used a small laryngoscope and it might be remembered that in looking for a diphtheritic membrane one might find a foreign body. In doing a laryngoscopy one should always have a small bronchoscope handy, and if the laryngoscope caused spasm or cyanosis it was not hard to pass the bronchoscope. It frequently happened, when a foreign body had been aspirated and was lodged in the larynx, that when the laryngoscope was passed the larynx relaxed and the object slipped through into the bronchi, so that by having the bronchoscope ready for use one might save a number of cases.

Dr. Koplik said there had never been anything more wonderful than the removing of a foreign body from the esophagus and bronchi and yet we should not forget that bronchoscopy was a very serious operation in children. He had noticed that Dr. Yankhauer took great precautions against accidents and he thought we should emphasize this fact. We should endeavor to get a history, though it was rarely that one did get a history, but one might find that there was a cough which had persisted for a long time, or a cough with a spasm that had persisted for a long time, when a foreign body was present in the bronchus. If in addition there was a certain amount of collapse of the lung, or a pneumonia, or the signs described by Dr. Yankhauer, which were frequently heard and frequently not heard, one might feel quite confident of the presence of a foreign body. Another point that should not be forgotten was that the *x*-ray did not always discover a foreign body. It was quite possible to have a bean, a melon seed, or a vegetable substance, which the *x*-ray would not reveal. Dr. Koplik referred to a series of cases of foreign body in the esophagus and lungs reported some ten years ago by Dr. Roche. These children ranged from early infancy to ten years of age. In five of them the foreign body was aspirated into the lung and all of these children recovered either by coughing up the foreign body, or else an abscess formed and the foreign body was eventually coughed up. It was well to remember not to allow yourself to become panicky because there was a history of no foreign body having been swallowed, for a study of these cases showed that they were not usually fatal even though an abscess formed. Dr. Koplik recalled that he had reported a case at the time Dr. Roche made his report in which a child had swallowed a peanut and an abscess formed in the lung, which was operated on and the child recovered. On the other hand, he knew of cases that had been bronchoscoped and died. Dr. Koplik related several such instances.

Dr. Eli Long said he must confess he could not see how a boy could be killed by looking into his bronchi. He felt qualified to speak of bronchoscopy and direct inspection in diphtheria and it was notable that the mortality had been reduced though the incidence of the disease had not been decreased. In many cases in which it was difficult to make a diagnosis between diphtheria and catarrhal inflammation anything that offered help was welcome and making a direct inspection as Dr. Gover had described was very easy and it was a great addition to our means of making a diagnosis.

Dr. Yankhauer, in closing, said that when a foreign body case was brought to be bronchoscoped soon after the swallowing or inhalation had occurred there was almost no danger from bronchoscopy. The mortality was very low. But when the foreign body had been present for weeks and pneumonia had developed bronchoscopy was then a much more serious procedure. Nevertheless, it must be done, because without removal of the foreign body abscess formation occurred and the large majority of these cases proved fatal. As he remembered the statistics showed that about 66 per cent of the cases in which foreign bodies had been inhaled had proved fatal if the foreign body had not been extracted, while something like 11 per cent. resulted in death when the foreign body was removed by the bronchoscope. We must get away from the idea that a foreign body would be coughed out when it was once impacted. The statement made by Dr. Gover and confirmed by Dr. Lynah, that direct examination of the larynx was a very simple matter was correct; it should be learned by every pediatrist and general practitioner. It was not much more difficult to make a direct laryngoscopic examination than to use a tongue depressor, at least in children.

Dr. Gover, in closing, stated that a part of the cases reported in this series were markedly stenotic, consequently he was always prepared when making the examination to pass a bronchoscope, intubate, or do a tracheotomy, should the condition of the patient demand it. As nearly as he could recall he had seen but two cases in which it was necessary to discontinue the examination on account of the increasing stenosis. In one of these the child was markedly croupy before beginning the laryngeal examination and he had to discontinue the examination and intubate the case This patient really demanded intubation before the examination. The other case was one that had been reintubated several times, and each time on removing the tube had to be reintubated. Many of these children when one first brought the larynx into view held their breath and completely closed the upper aperture of the larynx, but as soon as they inspired the larynx opened. Direct laryngoscopy was a very simple procedure and did not require many instruments or assistants.

SECTION ON SURGERY.

Stated Meeting, Held February 1, 1918.

Dr. Seward Erdman in the Chair.

Hypertonic Contracture of the Bladder Due to Injury of the Spine; Laminectomy; Cure.—Dr. Martin W. Ware presented this patient, who consulted him on January 5, 1918, for severe hemorrhage cystitis, great frequency of urination, and tenesmus with marked pain in the left lumbar region, a temperature of 102,

and much loss of weight. He stated that the patient gave a history of having fallen from a ladder two months before, sustaining a fracture of both ankles. Not having voided by the following morning, he was catheterized, and thereafter he was catheterized daily for six weeks. No paralysis of the limbs developed. The *x*-ray failed to show any injury of the spine. The fractures healed kindly and the retention of urine gave away to repeated frequent urination, amounting to almost constant dribbling. Examination showed the patient to be greatly emaciated and in a septic condition, as the result of the cystitis. The urine, painfully voided, was mixed with pus and blood; the finger in the rectum caused a gush of urine. The bladder was found very tender by rectum as well as suprapubic palpation. Tenderness extended along the course of the left ureter up to the left kidney. All the muscles of the left half of the abdomen and lumbar region were likewise tender. There was no anesthesia or paralysis of the limbs, nor was loss of any of the reflexes to be made out. The possibility of a spinal fracture was entertained, nevertheless, to account for the assumed isolated disturbance of the bladder mechanism. The following day after admission a suprapubic cystotomy was performed under general anesthesia. The operation was difficult, the peritoneal fold having been drawn far beneath the pubic arch, the abdomen was accidentally entered. The bladder when entered was found to admit the index finger and permitted the scantiest excursion of it. There was no projection, prostatic enlargement, calculus, or ulcer, but the bladder wall was fully one-half inch thick. A rubber drain was placed in the bladder. Immediately following the operation there was an improvement of the general condition. At the end of two weeks the urine cleared up and the drain was removed. After several weeks a complete closure of the bladder wound was effected. The bladder, which before the operation could only be distended to 30 c.c., could now be distended to 60 c.c. The patient, however, could not retain even the smallest amount of urine for any length of time. Attention was again directed to the possibility of a fracture of the spine. There was marked tenderness over the dorso-lumbar region of the left side and a kyphosis taking in the last dorsal and upper lumbar vertebrae. A very small butterfly shaped area of anesthesia was demonstrated in the anal fold, extending forward to the scrotum. There was no dissociation of heat and pain sensation. Dr. George Jacoby corroborated these findings and added the absence of the cremaster reflex and a slight increase of the left patellar and left abdominal reflexes. Dr. Jacoby concurred in the diagnosis of bony injury causing spinal pressure. The *x*-rays showed a compression fracture of the body of the twelfth dorsal and first lumbar vertebrae. A Laminectomy was advised. The spinous processes and the lamina of the twelfth dorsal and the first, second, and third lumbar vertebrae were removed down to the articular processes. Upon palpation a tense band was felt over the lower part of the exposed dura. The dura was incised between two guide sutures. The opening of the dura was enlarged up and down. The cord was then seen to be angulated, corresponding to the altered position of the fractured vertebræ. At the location of the band referred to above numbers of fine adhesions passed between the dura and the cord. No injury to the nerve roots was encountered. It was evident that resuturing of the dura would subject the cauda to pressure again, since the latter protruded beyond the slit in the dura. Therefore, a fascial graft from the fascia of the dorsal muscles an inch and one-half by one-half an inch was interposed, sutured in place with fine silk, the smooth side of the graft facing the cauda. Fluid from the cord no longer escaped. A slight, troublesome hemorrhage from the bone was controlled with bone wax. The muscles were sutured in layers and then the fascia and the skin. The operation lasted forty-five minutes. On the third day the suprapubic wound was opened and daily bladder irrigations given until the urine began to clear. At the end of four weeks the patient was discharged, able to walk freely and to void small quantities of urine. At no time after the operation was there any paralysis of the limbs or the rectum, or any undue abdominal distention. At the present time, one year after the operation, the return of the urinary function had set in. At no time was the sexual function in abeyance.

Fracture of Base of Skull; Ligation of Carotid Artery.—Dr. WARE presented this case also. He stated that the patient was a little boy who presented himself in July, 1917, with the history of having fallen down an area-way. The injury which he received was attended by loss of blood from the ear. He was taken to a hospital following an auditory examination. The ear was tamponed in order to stop the hemorrhage. Facial paralysis was present at once. After observing the boy for a few days an endoscopic examination was made, as result of which it was stated that the bleeding came from the ear drum. The hemorrhage stopped and the boy went home apparently all right. After a few days he had a recurrence of the hemorrhage and was brought back to the hospital and given the same treatment as before. An operation was contemplated and an *x*-ray examination ordered. While waiting for the *x*-ray another severe hemorrhage took place and hematoma formed just below the ear. A small incision was made and the hemotoma evacuated. No pulsating artery was noticed. After evacuating the hematoma the wound was tamponed and there was no further rise in temperature and no further bleeding. At the end of seven days the boy appeared to be out of danger. That night, however, he received a telephone message stating that the boy had had a very profuse hemorrhage and was almost exsanguinated. He then went to the hospital and gave the boy a transfusion of 500 c.c. of citrated blood, the father being the donor. He thought then that he was dealing with an injury of the internal carotid and tied that vessel. The transfusion was very effective. Six or seven days later there was another profuse hemorrhage, which was tamponed. He then thought possibly the hemorrhage was from the jugular sinus or the bulb under the petrous bone. He also took into consideration the possibility of the hemorrhage coming from the external carotid or a branch of the internal maxillary. He decided to tie the common carotid and when this was done the hemorrhage immediately stopped, so he was inclined to think that the hemorrhage came from that vessel; it seemed that if it had been from the internal carotid the boy would have died following any of the numerous hemorrhages. The boy recovered very rapidly. At the time of the first operation Dr. Ware stated that he noted an irregularity of the auditory canal and afterward there was an extension of the paralysis to the eye, mouth, and palate, so that his food regurgitated through the nose. This paralysis was now wearing off.

Tuberculous Peritonitis.—Dr. CHARLES P. L. PUTNAM presented this case, a woman who came to the hopsital in March, 1913, complaining of discomfort in the stomach, weakness, and exhaustion. She had worked throughout the Christmas rush in the basement of a department store. The physical examination of the lungs was negative, the von Pirquet test negative, and the blood count showed a leucopenia. There was an even rounding of the abdomen. The diagnosis of tuberculous peritonitis was made. An operation was performed and the patient placed out of doors. About three weeks after the operation, when the scar was healed, she developed a marked tuberculosis of the skin in that region and reacted very markedly to the von Pirquet test. After a three months' stay in the hospital, she made a good recovery. It was now five years and she had led an active life. She had, however, on several occasions been obliged to stop work and rest. In 1916, she developed hemoptysis and pulmonary tuberculosis was recognized. In the meantime she had been married and went to one of the speaker's colleagues asking for treatment so that she could become pregnant. She had a low grade of tuberculosis of the lungs, which was not active at the present time. The tuberculous peritonitis seemed to be cured, though there were tubercles scattered all over the parietal peritoneum at the time of the operation, and there were also tubercles in the pelvis. The mesenteric glands, the appendix, and ovaries were not specially involved.

Intraligamentous Fracture at the Ankle (Two Cases).—Dr. CHARLES R. L. PUTNAM presented these patients, who had had fractures of the lower end of the fibula,

because they illustrated what could be done with the ambulatory method of treatment. These women had been treated by the ambulatory method because they were working and would lose their places if not able to be about. In the treatment of fracture of the lower end of the fibula by the ambulatory method it was important to give sufficient protection by means of a plaster cast so that no deformity would be produced. In the one case it was about a year since the injury occurred and in the other about two months. In both the results were excellent.

Lipoma of Ascending Colon.—Dr. RICHARD LEWISOHN presented this patient, a woman fifty years of age, who was admitted to Mount Sinai Hospital on October 11, 1917. She had been complaining of right abdominal pain for two months. The attacks were severe, intermittent in character and of short duration. There was abdominal distension between the attacks. There was no blood in the stools. Physical examination revealed a moderate amount of myocarditis and nephritis, and a round nodular, very movable mass, at the level and to the right of the umbilicus. The *x*-ray showed a tumor protruding into the lumen of the ascending colon. At the operation, on October 17, a pendulous tumor the size of a plum was found, which originated from the inner wall of the ascending colon. The base of the tumor was soft and the distal portion felt hard and nodular. On account of the suspicion that the tumor might be malignant, the ascending colon with the ileocecal valve and the appendix were resected, both ends were closed, and the ileum and transverse colon united by a isoperistaltic lateral suture anastomosis. The patient made an uneventful recovery and left the hospital on November 7, 1917. Inspection of the specimen showed that they were dealing with pendulous lipoma, gangrenous in its distal half. The gangrene had evidently been caused by the constriction of the ileocecal valve in which the tumor had been caught at frequent intervals, thus causing obstructive symptoms of short duration. The microscopical diagnosis was gangrenous lipoma.

Carcinoma of Splenic Flexure.—Dr. RICHARD LEWISOHN presented this patient, a woman forty-one years of age, who was referred to him on June 27, 1917. She gave a history of having had an operation on her right kidney twelve years ago. This proved to be an abscess. Her present symptoms started two weeks ago with pain in the left upper quadrant and constipation. She had noticed some blood in her stools. Examination revealed an irregular mass in the left hypochondrium, hallotting into the loin. There was no abdominal distension. The previous history and physical findings suggested an affection of the left kidney, whereas her present clinical symptoms pointed to an intestinal neoplasm. She was immediately admitted to Mount Sinai Hospital for further study. The cystoscopic and roentgenological examination of the kidneys was negative. A barium enema showed a complete obstruction in the descending colon. At operation, on June 30, 1917, a carcinoma was found at the splenic flexure with a pin hole perforation posteriorly. The tumor was freed by splitting the peritoneum on its anterior and posterior attachments. The tumor was resected and both ends closed with purse string sutures. A lateral suture anastomosis restored the lumen of the gut. The specimen showed a large ulcerating circular carcinoma involving three and one-half inches of the intestine. The microscopical examination showed an adenocarcinoma. The patient left the hospital, on July 26, after an uneventful convalescence and was in perfect health at the present date.

Carcinoma of the Sigmoid Flexure; Complete Obstruction for Two Weeks; Three Stage Operation; Cure.—Dr. RICHARD LEWISOHN presented this patient, a woman seventy-four years of age, admitted to Mount Sinai Hospital on August 21, 1917. She had been perfectly well up to two weeks previous to her admission to the hospital. Since that time her bowels had not moved at all and her abdomen had gradually increased in size. She had been vomiting fecal material for two days before admission. Physical examination showed a very markedly distended abdomen. Rectal examination was negative. An immediate operation was performed for intestinal obstruction, which revealed a small annular, very movable carcinoma in the sigmoid flexure without glandular involvement; this was the cause of the obstruction. A typical Mikulicz Vorlagerung operation was performed. The afferent loop was opened on the following day and the tumor was removed on the sixth day. The microscopical diagnosis was adenocarcinoma. The patient left the hospital after an uneventful recovery on September 15. She was readmitted on November 25 for a closure of the artificial anus. Naturally they hesitated to submit this patient to another operation and explained to her the dangers of such a procedure at her advanced age. However, she insisted upon the closure of the anus. The speaker, therefore, performed another operation on December 5. After freeing from adhesions, the two ends of the gut were liberated and closed by an end to end anastomosis. No recurrence of the growth nor any glandular involvement was found. Her bowels moved on the sixth day. A small pin hole fecal fistula closed on the fifteenth day. She left the hospital on January 1, 1918, restored to her previous good health.

Dr. GEORGE BARRIE said that in reference to Dr. Ware's spine case, the *x*-rays were not especially good, but from what one could tell they showed what was known as Kümmel's spine. It was Kümmel of Hamburg who first described this injury, which was a crushing together of the vertebræ and not an actual break.

Dr. WARE thanked Dr. Barrie for his suggestion and agreed that the *x*-rays were not particularly good, but, nevertheless, they had helped to make them certain of the diagnosis. There were the three types of bladder paralysis and this case was of the third type. He believed it was the first case on record to show the fascial graft of the spine to make up the defect in the dura.

Dr. GEORGE H. SEMKEN recalled that the question of the ligation of the carotid was discussed at the last meeting of the Section. If this patient had injured his internal carotid it was doubtful if he would have survived the accident. In any event, ligation of the internal carotid in the neck would not have checked the hemorrhage, for immediate collateral circulation would be established through the circle of Willis. Dr. Ware's second supposition was that the patient had injured the internal maxillary branch of the external carotid; and for this, he ligated the common carotid. It was questionable whether this ligation would be effective in such an instance. After ligation of the common carotid, collateral circulation took place in the external carotid within a few minutes by retrograde flow through the internal carotid. If the internal carotid also had been tied (as well as the common carotid), collateral circulation in the external carotid was soon established, mainly through the free anastomoses between the opposite superior thyroids and the facials. Dr. Ware's patient did not have a continuous bleeding, but the hemorrhage came after intervals of four or five days. It was not wholly clear how much, if any, benefit came from the ligations.

Dr. WARE in closing said he did not have any delusions as to the effectiveness of ligating the internal or common carotid arteries and that he was familiar with the way in which the collateral circulation was reestablished in the circle of Willis. His object was simply to determine where the hemorrhage came from and, owing to the presence of the facial paralysis, the possibility of its being in the lateral sinus occurred to him; if it had been from the carotid it would probably have killed the child forthwith. A pulsation was seen, but it was not possible to say whether it was in the artery or vein at this point. The way the facts stood the hemorrhage had stopped after the ligation of the common carotid, but he was not at all sure in his own mind where the source of the hemorrhage was.

Dr. ROBERT T. MORRIS said that in regard to the case of tuberculous peritonitis there were several points worth while discussing. Why was there no von Pirquet reaction while the tuberculosis was confined to the peritoneum, but was distinctly active? Why was the skin involved later? That was certainly an unusual occurrence. All those who were dealing with tuberculous peritonitis almost daily would say that this was a most unusual condition to have the skin lesion follow the tuberculous peritonitis. No matter what one did for tuberculous peritonitis, whether one injected irritants or simply exposed the peritoneum to the air, the patients would recover in a large propor-

tion of the cases, because there was a hyperleucocytosis set up which destroyed the tubercle bacilli and that was very effective unless there was a very distinct focus remaining. The second unusual feature was the tuberculosis of the skin. It would be interesting to know if this had been treated with radiant light, since that might have been effective. A third interesting feature was that the tuberculous peritonitis was followed by lung tuberculosis and, while that was not a very common event, we might ask ourselves why it should not occur oftener than it does. Dr. Morris recalled a case in which the appendix was removed and found to be tuberculous, and the patient afterward developed general miliary tuberculosis. The patient recovered from this tuberculosis and later developed tuberculosis of both lungs and finally recovered from that. It was not often that a tuberculous peritonitis was followed by tuberculosis of the skin, and it was not often that there was a general tuberculosis following operation for a peritoneal tuberculosis.

Dr. WARE asked if the patient at the time of the peritoneal involvement had tuberculosis of the adnexa. If the adnexa were found to be tuberculous that might explain the etiology of the tuberculous peritonitis. The experience of Dr. Morris confirmed his own. He had had a patient with no symptoms of tuberculosis, but with an appendicitis. The appendix was removed and a good share of the abdomen explored and there was no indication of tuberculosis. Six months later the patient had a recurrence of his symptoms at the site of the ileocecal valve. Another laparotomy was performed and tubercles were found scattered all over the peritoneum and the intestines, yet the examination of the appendix six months before showed no evidence of tuberculosis. This patient developed a general tuberculous peritonitis and tuberculosis of the lungs. Dr. Ware said that by reporting this case he did not mean to convey the idea that he wished to discourage operations for tuberculous peritonitis.

Dr. WARE said he was much interested in the ambulatory treatment of fractures of the tibia. He had never seen the necessity of using pads under the casts. Everything depended upon having a properly fitted plaster bandage and in putting up the foot at right angles so that the patient could walk in a proper way, and he would then pound the sole of plaster into a soft pulp. Nothing was gained by using the pads; the real hold was from above and about the ankle and then the pressure of the foot on the ground gave the counter pressure. A little cotton at the center of the point of fracture was all that was necesssary.

Dr. ROBERT T. MORRIS said the question came up in this connection as to the necessity for so much apparatus when the patient walked with an intraligamentous fracture. The reason he brought the question up was that a physical instructor in one of the large universities formerly called all these fractures "sprains," and he always treated them by massage and directed the patient to keep on walking and not to stop at all. Lucas Championnière treated them in much the same way. Until the *x*-ray came into use we did not know that these so-called sprains of the ankle were mostly fractures. The question was how many of these fractures would recover under massage and walking without plaster. Dr. Morris said he was not advising this treatment, but wished to call attention to the fact that before we learned that these injuries which were supposed to be sprains were actual fractures, many patients made good recovery without the employment of splints or supports of any kind.

Dr. PUTNAM said he was very fortunate in having Dr. Morris bring out the three interesting points in this case. The patient when she came was in a very emaciated condition and no doubt had the lung condition at that time, although not recognized. It was unusual to have the lung involvement come after the tuberculous peritonitis. This patient had a leucopenia and failed to react to tuberculin, but later developed immunity, as indicated by the tubercular skin lesion, and developed the ability to protect her leucocytes. The skin lesion was treated by exposure to air without dressing. The patient was kept outdoors almost all the time in the recumbent position for three months.

Dr. PUTNAM said, with reference to his second case, that when he was an interne they had employed a German method of ambulatory treatment for fractures, with two inches of padding on the soles. They used it for Pott's fractures and the patient walked on the plaster cast. These cases that he had shown were both active people, who could not afford to stop work. He treated them for three days with hot and cold water and then put them in the plaster casts, using a reasonable amount of padding. The plaster was taken off on the eighteenth or nineteenth day. Most so-called sprains were in reality fractures, and it was better to have the ankle properly protected if the patient was going to use the foot.

The Surgical Treatment of Cancer of the Face.—Dr. GEORGE H. SEMKEN made this presentation, which was profusely illustrated by lantern slides. He said the regions considered were the skin, the eyelids, the nose, the parotid gland, and the lips. Two types of epithelioma were met—one, the basal celled; the other, the prickle or squamous celled. The former was of slow growth and remained localized throughout its whole course; the latter was more malignant, grew more rapidly, and eventually became generalized through the development of lymphatic gland and visceral metastases. Chronic irritation still must be considered the main factor in etiology. Apparently selective sites for the development of epithelioma were usually found to be regions of long continued irritation. Cancerous lesions of the face were usually single, but multiple lesions were not uncommon. The appearance of epithelioma was usually characteristic, though its forms were varied. Occasionally, however, it would resemble lupus or luetic lesions, especially the tertiary type; and differentiation from the mixed tumors was sometimes difficult. Simple suppurative inflammation in a long standing process had led to error at times. The best plan of treatment for cancer of the face was still a subject for discussion. Partial destruction or irritation through any form of chemical, ray, or surgical treatment was likely to stimulate the growth and might transform the basal celled type into the prickle celled type. Thorough destruction in one sitting was essential. The galvano-cautery was suitable for small growths, but excision was recommended for the larger ones. *X*-ray and radium treatments were not dependable as primary measures. Some cases of cancer were unimproved by these ray treatments; and in many others the repeated recurrences after apparent cure showed that complete destruction of the cancer had not been accomplished. In these cases the tumor finally acquired a resistance against the rays that made the ray treatment totally ineffective thereafter. Contrasting the recurrences after radiation treatment with those following properly performed surgical extirpation, it might be stated that in the surgical cases the only source of recurrence was the unrecognizable cancer extension, more or less remote from the periphery of the tumor; whereas, following radiation treatment, continued cancer growth might come from the tumor itself, as well as from these extensions, since the rays might not have completely destroyed all the cells of the cancer. Most unfortunate were those cases in which a small and easily destroyed epithelioma, that had been subjected to ray or chemical treatment, repeatedly recurred after apparent cure, and eventuated in an extensive erosion of the face. This was rarely met with after surgical extirpation. Surgical procedures must be radical to be effective. Conservative operations were never desirable in dealing with cancer. The problem thus becomes twofold—(1) the removal of the cancer, and (2) the repair of the resultant defect. Of the methods of repair, suture *in toto* was not usually practicable, because the excision was too wide to allow it. Partial suture and a Thiersch graft was the simplest method of wound closure. Thiersch skin grafts might even be successfully applied over extensive cut bone surfaces. Where skin and subcutaneous tissue were required for the closure of the defect, these might be taken in the form of pedunculated flaps from the cheek, forehead, or neck; or of migration flaps from the upper arm. Extensive defects might be closed in this manner. In the parotid gland the mixed tumor was the neoplasm most frequently encountered. Some of these tumors, though remaining benign, simulated cancer; some eventually became malignant. The parotid might be well exposed by a longitudinal incision, supplemented

by a transverse incision anteriorly, along the malar bone, and one posteriorly, under the ear. In the cases of cancer the longitudinal incision must be prolonged in the neck, along the anterior border of the sterno-cleido-mastoid, so that the cervical lymph nodes also might be removed. The removal of the parotid necessitates the division of the facial nerve. The added removal of the lymph nodes in the upper part of the neck would be followed by a persistent edema of that side of the face. In the dissection of the jugular fossa, a good landmark was the fine fascia under the digastric muscle. Cancers of the lip presented a different problem from the other cancers of the face, because the lip cancers were almost invariably of the prickle cell type. Hence, the removal of the respective, associated lymph nodes became the first duty, no matter how small the lip cancer might be. In early cases it was sufficient to remove the submental and submaxillary groups, with the submaxillary salivary gland, through Kocher's incision. It was safer, however, to remove the carotid and digastric packets also; and for this purpose the incision along the sternocleidomastoid should be extended. For the lip operation wedge excision and suture of the lip was the usual procedure. Where larger areas required excision, closure might be made by means of flaps taken from the cheek or neck. In cases of total or sub-total resection of the lower lip, Dr. Semken said that the method of choice was the Dieffenbach operation.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, Wednesday, June 5, 1918.

DR. THOMAS R. NEILSON IN THE CHAIR.

Psychological Examining in the Army. — MAJOR ROBERT M. YERKES, San.C., N. A., said that the principal purposes of the examining of drafted men and of company officers were to assist the psychiatrist and neurologist in eliminating the mentally unfit; to assist the personnel officer in classifying soldiers; and to aid all officers in the selection of men who were fit for special responsibility or for training in officers' training camps. Methods for this work had been devised during the summer of 1917 and had since been greatly developed. Approximately 300,000 men had been examined. Of these 10,000 were officers and approximately 25,000 were students in officers' training camps. At least 50,000 psychological examinations, he said, were being made a week. The work, he believed, had more important significance for the personnel bureau of the army than for the medical department. The procedure of examining was outlined as follows: A group of from 100 to 300 drafted men reporting in examining room was divided into two sections of men, consisting of those who could read and write English fairly well, and those who because of foreign birth or lack of education were illiterate in English. The literate group was then given one form of examination; the illiterate an entirely different sort of examination, which did not require either reading or writing. A man failing in either or both examinations was given individual examination. Several varieties of individual examination were said to be used and were applied in accordance with the characteristics of the individual to be examined. The personnel for this work Major Yerkes describes as of very high quality. More than seventy officers had been trained for work in military psychology at the School in Military Psychology, Medical Officers' Training Camp, Fort Oglethorpe, Georgia. These men, he said, were now conducting psychological examinations in the various army training camps. At the school above mentioned about two hundred and fifty of the enlisted men had been given regular training in military psychology.

Neuropsychiatry in the Army.—COLONEL PEARCE BAILEY, M.C., N.A., said that in the examinations to determine whether or not men were to be allowed to go overseas, one method employed consisted of a rapid survey of the whole organization—of all the troops, officers included. All passed under the eye of one or more neuropsychiatrists. They were given a test of about a minute and a half, long enough to test the knee jerk, tremors of hand and tongue and the reaction to the immediate situation. This test determined the indication for a more extended examination. The other method, used much in the first draft and before the neuropsychiatry department was organized, was a method of referred cases, in which only those referred by other officers, line or medical, were examined. In this method there had been more cooperation from the laymen than from the medical officers. At the present time, he said, very close cooperation was had from everyone. The psychiatrist did not recommend a discharge without such recommendation going through the disability boards and it thus was endorsed by at least three non-specialists. It was believed that by the means employed in the work neuropsychiatry would reach a point of preventive medicine of high significance. In the reconstruction of soldiers neuropsychiatry it was believed would also have an important function. Examiners were stationed at the camps, depots, and ports of embarkation. A certain percentage of the men were found to be nervously unfit. Not many neurological cases had yet been returned from the other side. A hospital at Plattsburg had just been secured to which patients were transferred from the cantonments as fast as possible. How these cases differ from the war neuroses of the other side the author said was not known, but he was confident that there were no neurotic symptoms produced on the front not to be found in this country. A much smaller number of insane requiring hospital treatment had been found than had been anticipated. A contributing factor to this smaller percentage was the fact of the examinations having been made at the point of entrance to the army. The States, with but few exceptions, Colonel Bailey said, had cooperated in caring for their insane when insanity developed immediately after entrance into the army. While only 300 had gone back, it had been shown that army life rendered a neurotic the subject of custodial care. There had been less than 500 cases of drug addicts. If the number proved to be very much above this a special camp, it was said, would be established for the treatment of such patients, after which they would be drilled for military service. There were at present in the neuropsychiatric department some 360 officers, about one-third of whom were on the other side. They had come chiefly from the State hospitals. Requests had been received to send men with neurological training and on this account it had recently been necessary to decline at least one hundred applications for positions to be filled. Men who were able to speak Italian and Spanish were said to be especially wanted.

Dr. F. X. DERCUM said that the symptoms of the psychoneuroses met with in the army could be grouped under the familiar clinical pictures seen in civil life. Curiously enough, they occurred largely among the draftees just as in the out-patient departments and hospital wards; they were less frequent among officers, just as they were less frequent among the better classes in civil life. It was most important, he believed, that these cases be excluded at the source. So far as the psychological tests were concerned, Dr. Dercum thought that a man might not be able to pass the tests involved and yet make a very efficient soldier. Such tests were not, he observed, a measure of a man's physical strength, of his endurance, of his ability to shoot, of his personal courage. Many a man had sprung from the ranks who did not have the qualities of mind enabling him to pass through such a series of complicated tests, Dr. Dercum said, and yet had made an efficient officer.

Dr. THOMAS MCCRAE expressed the opinion that if anyone who has been abroad working on the medical side in the war were asked who had the best chance of being of use, he would answer the neurologist. This truth he did not believe to be sufficiently recognized. He had urged upon every man connected with the formation of a military hospital unit the necessity of having a well qualified neurologist on the staff. As head of the medical side of a hospital without a neurologist he had had to meet the neurological problems arising among 2000 patients. Many cases of nerve injury were extremely complicated and the decision as to treatment was often a difficult matter. He strongly emphasized the need in this war for the neurologist.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO BOARD OF MEDICAL EXAMINERS.

Denver, April 2, 1918.

ANATOMY.

1. Describe the spinal column as a whole.
2. Describe a typical lumbar vertebra.
3. Give attachments, action and nerve supply of the following muscles: Deltoid, pronator radii teres, sartorius and sternomastoid.
4. Give the course and branches of the femoral artery.
5. Explain the anatomical conditions which favor the production of femoral hernia.
6. What structures are supplied by the following nerves: Phrenic, third cranial, musculospiral?
7. Explain the anatomical basis for hemorrhage from the stomach in cirrhosis of the liver.
8. Name and describe the valves of the heart.
9. Describe the knee joint.
10. Describe the trachea.

PHYSIOLOGY.

1. Describe the lymphatic system and tell its function.
2. What part of the brain controls coordination of muscular action? How is it done?
3. Give the various enzymes that would act when a piece of bread and butter is eaten.
4. Give the factors concerned in the regulation of the beat of the heart.
5. What is the meaning of systolic and diastolic used in relation to blood pressure? How produced?
6. Describe reflex action.
7. Describe the changes that take place in the eye when vision is directed to a near object.
8. Name four excretory organs of the body, and give their functions.
9. What are the functions of the medulla oblongata?
10. How is secretion in the salivary glands effected?

CHEMISTRY.

1. Define chemistry; state how it is divided; give examples.
2. Define the terms atomic weight, atomic volume, molecular weight, molecular volume.
3. Explain the significance of the prefixes hydro-, hypo-, hyper-, sub-, bi-, nitro-, and the suffixes -ous, -ic, -ite, -ate and -ide.
4. Describe (*a*) distillation, (*b*) filtration, and (*c*) precipitation, as applied to process for purifying drinking water.
5. Mention some substances used for disinfection after the prevalence of contagious disease and explain their reaction.
6. What is hemoglobin? Name its properties and functions and state how it may be recognized.
7. Give the uses of the urinometer. State its importance as an aid in diagnosis and method of determining specific gravity of urine insufficient for urinometer.
8. What chemical changes take place as a result of muscular action.
9. Describe pepsin and name the medium in which it is most active.
10. Define fats and give the names and formulas of three fats.

ANSWERS.

ANATOMY.

1. The *spinal column* is flexible column formed by the vertebræ superimposed one on the other, and of intervertebral substance. The vertebræ are seven in the cervical region, twelve in the dorsal, five in the lumbar, five in the sacral, and four in the coccygeal. The two last sets unite to make the sacrum and coccyx. It is about 26 inches long. Viewed laterally the spine shows four curves, the cervical, dorsal, lumbar, and pelvic; these curves are alternately convex and concave (from before backwards). Through the center of the spine is the spinal canal for the spinal cord. The *general characters of a vertebra* are: Body or centrum, arch, two pedicles, two laminæ, four articular processes, two transverse processes, and one spinal process.

2. The *lumbar vertebræ* have a large body, wider transversely, and with no facet or demi-facet; the laminæ are short and thick; the spinous process is horizontal; the transverse processes are "rudimentary"; the superior articular process is directed inward and slightly backward; the inferior articular process is directed outward and slightly forward; the spinal foramen is larger and triangular.

3. DELTOID. *Origin:* From the outer third of anterior border and upper surface of the clavicle, from the outer margin and upper surface of the acromion process, and from the lower edge of the spine of the scapula. *Insertion:* Into the deltoid impression on the middle of the outer side of the shaft of the humerus. *Action:* It raises the arm from the side so as to bring it at right angles with the body; its anterior fibres draw the arm forward; its posterior fibres draw the arm backward. *Nerve supply:* The circumflex.

PRONATOR RADII TERES. *Origin:* From the front and upper part of the internal epicondyle and the supracondylar ridge of the humerus; the common tendon, and intermuscular septa; also from the coronoid process of the ulna. *Insertion:* Center of outer surface of radius. *Action:* To pronate the forearm and assist in flexing the elbow joint. *Nerve supply:* Median nerve.

SARTORIUS. *Origin:* Anterior superior spine of ilium and upper part of notch. *Insertion:* Internal surface of shaft of tibia, just behind the tubercle. *Action:* It flexes the knee joint, the hip joint, and the pelvis upon the thigh; it is an internal rotator of the leg, and an external rotator and abductor of the thigh. *Nerve supply:* Anterior crural nerve.

STERNOMASTOID. *Origin:* Upper and outer part of the anterior surface of the manubrium sterni, and upper surface of the clavicle at its sternal end. *Insertion:* Outer surface of mastoid process of the temporal bone, and outer part of the superior curved line of the occipital bone. *Action:* To flex the head to the same side as the muscle; the two acting together flex the head on the thorax and also raise the upper thoracic wall in forced inspiration. *Nerve supply:* The spinal accessory nerve and a branch from the cervical plexus.

4. The *femoral artery* begins at Poupart's ligament; it is the continuation of the external iliac, and passes down the fore part and inner side of the thigh, to terminate at the opening in the adductor magnus at the junction of the middle with the lower third of the thigh, where it becomes the popliteal artery. *Branches:* Superficial epigastric, superficial circumflex iliac, superficial external pudic, deep external pudic, muscular, anastomotica magna, and profunda femoris (with branches: external circumflex, internal circumflex, and three perforating).

5. *Femoral hernia* leaves the abdomen through the femoral ring and descends into the femoral canal; this canal is funnel-shaped, is about ½ inch in length, and ends at the saphenous opening. Femoral hernia is always *acquired*, and has a sac. Its course is first vertical, then forward, then upward over Poupart's ligament. The femoral ring is, naturally, a weak spot in the abdominal cavity; further, in women the pelvis is wider, the ring is larger, and Gimbernat's ligament is less developed than in men. The canal is funnel-shaped.

6. The *phrenic nerve* supplies: The diaphragm; it also supplies twigs to the pericardium and the mediastinal pleura.

The *third cranial nerve* supplies: The levator palpebræ superioris, superior rectus, inferior rectus, internal rectus, and inferior oblique muscles of the eye, and the ciliary muscle.

The *musculospiral nerve* supplies: The triceps, anconeus, brachialis anticus, extensor carpi radialis longior, supinator longus, and the skin of the back of the arm and forearm.

7. The gastric veins (which enter into the portal vein) and the esophageal veins (which enter the general circulation through the inferior thyroid veins) anastomose. Cirrhosis of the liver causes pressure on the portal vein and hemorrhage results in the stomach (and elsewhere where the portal and general venous circulations meet).

8. VALVES OF THE HEART.—"The *mitral* and *tricuspid*

valves are situated in the left and right ventricles respectively, at the auriculo-ventricular orifices, and prevent the passage of blood into the auricles during the ventricular systole. They consist of flaps or cusps, two in the mitral and three in the tricuspid, connected by their bases to the auriculo-ventricular orifices; their free margins and lower surfaces give attachment to the chordæ tendineæ which connect them with the musculi papillares. They are formed of a duplicature of the lining membrane of the heart, strengthened by connective tissues. During the ventricular systole, the pressure of the blood in the ventricles presses their free edges, or rather their marginal surfaces, together, the musculi papillares regulating the tension of the chordæ and preventing the valves from becoming retroverted into the auricles.

"The *semilunar valves* guard the aortic and pulmonary openings. They consist of three semicircular folds attached by the convex margin to the wall of the artery at its junction with the ventricle, and are formed by a reduplication of the lining membrane strengthened by fibrous tissue. In the center of each free margin is a little nodule, the corpus Arantii, the three meeting in the center when the valves are closed. On each side of the corpora Arantii is a thin semilunar marginal surface, where the fibrous tissue is absent, called the lunula; these surfaces come in contact when the valves close."—(Ashby's *Notes on Physiology*.)

The *Eustachian valve* is found in the right auricle, between the interior margin of the postcava and the auriculo-ventricular orifice. It is semilunar in shape and is formed by a duplicature of the lining membrane of the auricle. The *coronary valve* is a semicircular fold of the lining of the membrane of the right auricle; it protects the orifice of the coronary sinus.

9. The *knee joint* is a ginglymus, and is formed by the condyles of the femur, the head of the tibia, and the patella. "The *external ligaments*, the *anterior* or *ligamentum patellæ* is the continuation of the tendon of the triceps extensor. Above it occupies the apex and rough marking on the lower and posterior surface of the patella; below it is attached to the lower part of the tubercle of the tibia. There is a bursa between the upper part of the tubercle and the ligament. The *posterior ligement* (*ligamentum posticum Winslowii*), broad and thin, covers the back of the joint. It consists of a central and two lateral parts. The lateral parts spring above from the femur above the condyles and are attached below to the head of the tibia. The central part is derived from an expansion of the semimembranosus tendon, and passes from the inner tuberosity of the tibia to the inner side of the upper part of the outer condyle of the femur. The *internal lateral ligament*, broad and flat, is attached above to the inner condyle of the femur; below, to the margin of the inner tuberosity, to the internal fibrocartilage, and to the inner surface of the shaft of the tibia for 1½ inches. The *long external lateral ligament*, a rounded cord, is attached above to the external condyle of the femur, and below to the external part of the head of the fibula, dividing the biceps tendon into two parts, a bursa intervening. The *short external lateral ligament*, very indistinct, lies parallel and behind the preceding, attached above to the outer condyle of the femur, and below to the styloid process of the fibula. The *capsular ligament*, thin, fills up the intervals between the special ligaments; it is attached to the margins of the articular surfaces of the bones, and blends with the fascia lata of the thigh: above it receives expansions from the vasti (*lateral patellar* ligaments).

"The *Internal Ligaments:* The *anterior* or *external crucial ligament* is attached to the depression in front of the spine of the tibia and to the external semilunar fibrocartilage; it passes upwards, backwards, and outwards to the posterior part of the inner side of the external condyle of the femur. The *posterior* or *internal crucial ligament* is attached to a depression behind the spine of the tibia, to the popliteal notch, and the posterior border of external semilunar fibrocartilage, this latter slip being sometimes called the *ligament of Wrisberg;* it passes upwards, forwards, and inwards, the posterior fibres attached by side of oblique curve of inner condyle, the anterior ones to the fore part of intercondylar fossa and to the anterior part of the outer surface of the inner condyle. The *semilunar cartilages* are thicker at the circumferences than at the central margins and serve to deepen the cavities for the head of the femur. The *internal semilunar cartilage* is oval in shape, the anteroposterior diameter being the longer. Its anterior extremity is attached to the tibia in front of the anterior crucial ligament, and the posterior extremity in front of the posterior crucial ligament. The *external semilunar cartilage* is nearly circular; its anterior extremity is attached to the tibia in front of the spine, the posterior extremity to the back of the spine."—(*Aids to Anatomy.*)

10. The *trachea* begins at the level of the cricoid cartilage, in front of the sixth cervical vertebra. It is a wide tube, about four and a half inches long, kept patent by a series of cartilaginous rings; posteriorly these rings are incomplete, and so the trachea is flattened behind. It lies in the median line of the body, enters the chest through the upper thoracic opening, and ends by dividing into the two bronchi opposite the disc between the fourth and fifth thoracic vertebræ. It lies upon the esophagus.

PHYSIOLOGY.

1. The lymphatic system consists of: lymphatic glands, lymph vessels, perivascular lymph spaces, the lymph canalicular system, the pericardial, pleural, peritoneal, and synovial cavities, and the lacteals.

The lymphatic circulation is, strictly speaking, not a circulation at all, since the lymph flows only in one direction, namely, toward the heart. The lymph capillaries take up any excess of the blood plasma which is not required for the nutrition of the tissues. These capillaries consist of a single layer of epithelium, and empty themselves into vessels very like the veins. The lymph vessels are well provided with valves, which are so closely approximated as to give the vessels a beaded appearance. All the lymphatic vessels, except those of the right upper half of the body, empty into the thoracic duct, which terminates in the left subclavian vein, where the left internal jugular vein also enters. Those from the right upper half of the body discharge into the right lymphatic duct, which, in turn, empties into the right subclavian vein at its junction with the right internal jugular vein.

The forces concerned in the circulation of the lymph are: (1) The pressure of the blood in the blood-vessels; (2) thoracic aspiration; (3) muscular contractions of the voluntary muscles; (4) contractions of the intestine; (5) the action of the valves in the lacteals and lymphatics.

The *function of the lymphatic system* is to provide the tissues with material necessary to their functional activity, growth, and repair; to receive from the tissues their waste products; and to convey the products of digestion and absorption to the blood-current.

The lymph capillaries differ from the blood-capillaries, chiefly, in their larger and very variable caliber and also in their numerous communications with the lymph spaces. The lymph vessels in several have thinner coats than the blood-vessels; and the valves in the lymph vessels are much more abundant than in the veins.

2. The cerebellum is the center for the control of coordination of muscular action. "Though it is not known how the cerebellum selects and coordinates groups of muscles for the performance of any complex movement, it is known that its activity is largely reflex in origin and excited by impulses reflected to it from peripheral organs. In this as in other forms of reflex activity the mechanism involves (1) afferent nerves, *e. g.*, cutaneous, muscle, optic, and vestibular, and their related end-organs, tactile corpuscles, muscle spindles, retina, and semicircular canals, all indirectly connected with (2) the cerebellar centers; (3) efferent nerves indirectly connected with (4) the general musculature of the body. Both station and progression are directly dependent on the development and transmission of afferent impulses from the previously mentioned peripheral sense-organs to the cerebellum. Tactile, muscle, visual, aand labyrinthine impressions and sensations not only cooperate in the development and organization of the motor adjustments necessary to the maintenance of the equilibrium and locomotive coordination, but even after their organization they are necessary to the excitation of cere-

bellar activity. The manner in which they lead to the development of this capability on the part of the cerebellum is conjectural."—(Brubaker's *Physiology.*)

3. *Bread* consists of proteid, fat, carbohydrate, salts, and water. *Butter* consists of fat, a little proteid, and water. In the *mouth*, the ptyalin of the saliva changes starch into dextrin and sugar; in the *stomach*, the proteids are changed by the pepsin into proteoses and peptones; in the *small intestine*, the proteids are further changed by the trypsin into proteoses and peptones aand afterwards into polypeptides and amino-acids; starches are converted by the amylopsin into maltose; fats are emulsified and saponified.

4. "The *neurogenic theory of heart beat* supposes that the internal stimulus to the heart beat arises within the nerve cells which are present at the venous end of the heart, and that the excitatory wave is conducted by nerves."

"The *myogenic theory* supposes that the heart muscle itself possesses the property of automatic rhythmicality, and that this property is most marked at the venous end of the heart, and at the sinu-auricular and auriculo-ventricular junctions. The contraction wave is generated at the venous end of the heart in the muscle, and, in virtue of the conductivity of cardiac muscle, spreads over the muscle tissue of the auricles, and thence over the ventricles. In other words, the contraction wave commences in muscle and is conducted by muscle. The muscular continuity of the auricles and ventricles is brought about by the auriculo-ventricular bundle of His."—(Lyle's *Physiology.*)

"*Automaticity.*—Inasmuch as the heart continues to contract in a perfectly rhythmic manner after removal from the body and apparently without the aid of an external stimulus, it is said that the heart-muscle is automatic or spontaneous in action. Strictly speaking, however, this is not the case, for the reason that all movement, that of the heart included, is the resultant of the action of natural causes, though their true nature may be beyond the reach of present methods of investigation."—(Brubaker's *Physiology.*)

5. "The maximum pressure caused by the systole of the heart, the apex of the pulse wave, is spoken of as *systolic pressure;* the minimum pressure in the artery —that is the pressure at the end of the diastole of the heart, or the bottom of the pulse wave, is known as the *diastolic pressure.* . . . In speaking of the pressure in the blood-vessels we refer usually to what is called the *mean pressure.* It is obvious that, so far as the larger arteries are concerned, the *mean pressure* is only a convenient expression for the average pressure during a certain period. If we know at any moment the systolic and the diastolic pressure in an artery we can estimate the mean pressure with approximate accuracy by taking the arithmetical mean of the two figures."—(Howell.)

6. *Reflex actions* are involuntary or unconscious movements, due to suitable stimuli. They depend upon the integrity of the *reflex arc*, which is a complex made up of: (1) A surface capable of receiving an impression; (2) an afferent nerve; (3) a nerve cell capable of receiving and also of sending out impulses; (4) an efferent nerve, and (5) a surface capable of responding to the impulse conveyed by the efferent nerve.

Example: The patellar reflex consists of a contraction of the extensor muscles of the leg and a movement of the foot forward when the ligamentum patellæ is struck; the quadriceps extensor must first be slightly stretched by putting one knee over the other. Its integrity depends upon a healthy condition of the entire reflex arc, consisting of tendon, afferent or sensory nerve, posterior roots, and anterior horn of the spinal cord, the efferent or motor nerve, and the muscle itself.

7. The eye is made up of the following membranes, arranged in a concentric manner, from without inward: The sclerotic and cornea; the choroid and iris, and the retina. Within these are enclosed the refracting media: The aqueous humor, the crystalline lens, and the vitreous humor; the cornea is also a refracting medium. These media "have different refractive indices, which, when acting together, refract all rays of light in such a manner that they come to a focus on the retina, and so prevent chromatic aberration. In the emmetropic or normal eye adequate refraction is secured by the mechanism of accommodation, as follows: (*a*) Rays of light which fall on the lens in parallel lines are refracted in such a way that they are brought to a focus in the retina. These rays come from a point infinitely far away. (*b*) If the rays of light come from a near point they diverge as they pass to the lens, and if the lens retained its shape they would be brought to a focus behind the retina. But as the eyes converge to look upon the near object, a stimulus passes up from some unknown stimulated point to the nucleus of origin of the third cranial nerve, and is reflected back along the third cranial nerve to the ciliary muscle which contracts. This pulls forward the choroid, to which is attached the hyaloid membrane, which becomes continuous with the capsule of the lens. The lens capsule thus becomes slacker, and therefore the lens, in virtue of its elasticity, bulges chiefly forward. Hence its anterior surface becomes more convex, *i.e.* capable of refracting the divergent rays in such a manner as to bring them to a focus on the retina."—(Lack's *Introduction to Physiology.*)

8. *Four excretory organs of the body:*—Lungs, skin, kidneys, and large intestines.

Functions of lungs:—To take in oxygen, and to excrete carbon dioxide and water.

Functions of the skin:—To eliminate water, carbon dioxide, urea, salts; protection; secretion; absorption; sensation; special sense of touch; and regulation of body temperature.

Functions of kidneys:—To eliminate water, urea, nitrogenous matter, inorganic salts (and, generally, the secretion of urine).

Functions of large intestines:—To eliminate the indigestible and unabsorbed substances from the food, with secretions from liver and pancreas.

9. The *functions of the medulla oblongata:* (1) It is a conductor of nervous impulses or impressions from the cord to the cerebrum, from the brain to the spinal cord, also of coordinating impulses from the cerebellum to the cord; (2) it contains collections of gray matter which serve as special nerve centers for the following functions or actions: respiration, salivary secretion, mastication, sucking, deglutition, vomiting, voice, facial expression; it also contains the cardiac and vasomotor centers.

10. *The mode of secretion of saliva.*—"The secretion of saliva is a complex act and involves the cooperation of gland cells, blood vessels, efferent and afferent nerves contained in different cranial nerves, and a central mechanism by which they are excited to and coordinated in activity. The central mechanism is located in the medulla oblongata in the gray matter beneath the floor of the fourth ventricle and subject to cerebral and surface stimulation. During the intervals of mouth digestion the glands are practically at rest as far as the discharge of saliva is concerned. The cells, however, are actively engaged in absorbing from the surrounding lymph spaces materials derived from the blood, out of which they construct their characteristic constituents. The blood vessels possess that degree of dilatation necessary for nutritive purposes. With the development of the sensation of hunger, the sight and the odor of agreeable foods develop visual and olfactory sensations, which give rise to psychic states more or less agreeable. With their development the entire mechanism is excited to activity and a more or less abundant discharge of saliva into the mouth frequently takes place. This is, therefore, known as a psychic secretion. The fluid thus secreted has given rise to the expression "watering of the mouth." With the introduction of food into the mouth and the stimulation of afferent nerves (nerves of general sensibility and nerves of taste) and the onset of mastication, the blood vessels suddenly dilate, the blood supply is increased, and the gland cells begin to discharge water, inorganic salts, and their organic constituents into the lumen of the acinus, materials that collectively constitute the saliva characteristic of any one of the glands. This continues until mastication ceases, when all the structures return to their former condition of relative inactivity. . . . The *afferent* nerves are the lingual and buccal branches of the trigeminal nerve; taste fibres in the chorda tympani; and taste fibres in the glossopharyngeal. The *efferent* nerves are the chorda tympani and its post-ganglionic continuations for the submaxillary and sublingual glands; the glossopharyngeal

nerve and its post-ganglionic continuations contained in the auriculotemporal branch of the trigeminal nerve for the parotid gland. The sympathetic nerve, both pre- and post-ganglionic fibres, for all the glands."—(From Brubaker's *Physiology.*)

CHEMISTRY.

1. *Chemistry* is that branch of science which deals with the composition of substances, their changes in composition, and the laws governing such changes.

There is no recognized division; the following are the chief branches:

Inorganic chemistry is the chemistry of such elements and compounds as do not contain carbon.

Organic chemistry is the chemistry of the carbon compounds.

Physiological chemistry is the chemistry of the living organism and its various processes.

Synthetic chemistry is that branch of chemistry which is concerned with the building up of compounds out of simpler compounds or elements.

Analytical chemistry deals with the determination of the constituents of a chemical compound or of a mixture of compounds. When only the names of the constituents are sought, the determination is called *qualitative;* and *quantitative* when the amount present is also ascertained.

2. *Atomic weight* is the weight of an atom of an element as compared with the weight of an atom of hydrogen.

Atomic volume is the space occupied by the quantity of an element as compared with its atomic weight; it is the specific gravity of the element divided by its atomic weight.

Molecular weight is the weight of a molecule of a substance as compared with the weight of an atom of hydrogen; it is the sum of the atomic weights.

Molecular volume is the volume occupied by one gram-molecule of a gas or liquid under normal conditions.

3. *Hydro-* denotes the presence of water, or of hydrogen; or it indicates a hydracid.

Hypo- denotes an acid or a salt with the smallest number of oxygen atoms.

Hyper- denotes an acid or a salt with the greatest number of oxygen atoms.

Sub- denotes a basic salt, or a salt in which only part of the replaceable hydrogen of the acid has been eliminated.

Bi- denotes two atoms or a double quantity of an element.

Nitro- denotes combination with the radical NO_2.

-ous indicates an acid containing a smaller amount of oxygen than is found in the -ic acid; also a compound in which an element has the lower of two possible valencies.

-ic denotes an acid containing more oxygen than is found in the -ous acid; also a compound in which an element has the higher of two possible valencies.

-ite denotes a salt derived from an -ous acid.

-ate denotes a salt derived from an -ic acid.

-ide denotes a binary compound; also a salt derived from a hydracid.

4. In *distillation* the water is boiled and the steam is then condensed.

In *filtration* the water is passed through a porous material and the suspended impurities are thus more or less completely removed.

In *precipitation,* alum or a ferric salt is added to the water; this forms a gelatinous precipitate with many of the impurities and carries them down with it, mechanically; after a time the water above the precipitate is drawn off for use.

5. DISINFECTANTS: (1) *Formaldehyde,* due to the facility with which it parts with its oxygen. (2) *Potassium permanganate,* due to the large amount of oxygen which it contains ($KMnO_4$), and the readiness with which it parts with the same. (3) *Phenol* is a germicide; so, too, is (4) *bichloride of mercury.*

According to Rosenau, disinfectants destroy bacteria in four ways: (1) Destruction by oxidation, as ozone, chlorinated lime, potassium permanganate and the halogens. (2) Destruction by ionic poison with coagulation, as the metallic salts. (3) Destruction by coagulation and poisoning not ionic in character, as carbolic acid and phenol derivatives. (4) Destruction by emulsoid action, that is, through Brownian movement and absorption.

6. *Hemoglobin* is the name given to the pigment found in the red blood corpuscles; it is a crystalline substance, and consists of the elements carbon, hydrogen, oxygen, nitrogen and sulphur and iron; the molecule is complex and heavy. When pure, it is a crystalline solid, more or less soluble in water, soluble in dilute alcohol, red or purple in color. It takes up oxygen from the air in the lungs and is then called oxyhemoglobin; it carries the oxygen to the tissues, where it parts with it, and becomes reduced hemoglobin. It forms a very stable compound with carbon monoxide. On hydrolysis it yields a simple protein and hemochromogen which latter contains iron and is readily oxidized to hematin.

7. The *urinometer* is a hydrometer used for obtaining the specific gravity of the urine. Normally the specific gravity of the twenty-four hours' urine is about from 1015 to 1025. Marked deviations from these figures denote something abnormal or pathological. The total solids in the urine may be roughly calculated by multiplying the last two figures of the specific gravity by two; this gives the number of grams of solids in one liter of urine. As a rule, a high specific gravity denotes diabetes mellitus, fever, hemorrhages, severe diarrhea, profuse perspiration; a low specific gravity is found in albuminuria, chronic interstitial nephritis, hysteria, and diabetes insipidus.

If the quantity of urine available is not sufficient to float the urinometer it may be diluted with an equal volume of water; the specific gravity is then taken and the last two figures are multiplied by two, to get the true specific gravity.

8. *The following chemical changes take place as a result of muscular action:* (1) Oxygen is used up; (2) carbon dioxide is produced; (3) sarcolactic acid is developed; (4) the reaction becomes acid; (5) the amount of glycogen is reduced.

9. *Pepsin* is a proteolytic extract obtained from the mucous membrane of the stomach of the pig; it is capable of digesting no less than 3000 parts of coagulated egg-albumen. It is sold in the form of white or yellowish scales or powder; it has an acid reaction, and a very slight taste and odor; it is nearly insoluble in alcohol, and dissolves in about fifty parts of water. It is most active in an acid medium.

10. *Fats* are mixtures of the esters of glycerol and a fatty acid. *Three fats:* Tripalmitin, $C_3H_5(O.C_{16}H_{31}O)_3$; Tristearin, $C_3H_5(O.C_{18}H_{35}O)_3$; Triolein, $C_3H_5(O.C_{18}H_{33}O)_3$.

TREATMENT OF INOPERABLE CANCER OF THE BREAST BY CHEMICAL EXTIRPATION.*

BY CHARLES WILLIAM STROBELL, M.D.,

NEW YORK.

GYNECOLOGIST WEST SIDE DISPENSARY HOSPITAL; ATTENDING CLINICAL ASST. MEMORIAL HOSPITAL; ATTENDING CLINICAL ASST. NEW YORK CANCER HOSPITAL

IN my choice of a subject tonight I am keenly aware that it may elicit much adverse criticism. That it should arouse discussion is of course as it should be, and I may state frankly that I shall be disappointed if criticism be not forthcoming, but not of course perfunctory registration of merely adverse opinion.

Naturally, I hope and expect to demonstrate that my method is impregnable to fair-minded and sincere assaults; but if there is any feature of it that is susceptible of betterment, and especially if my arguments have any basis of fallacy, I hope I shall

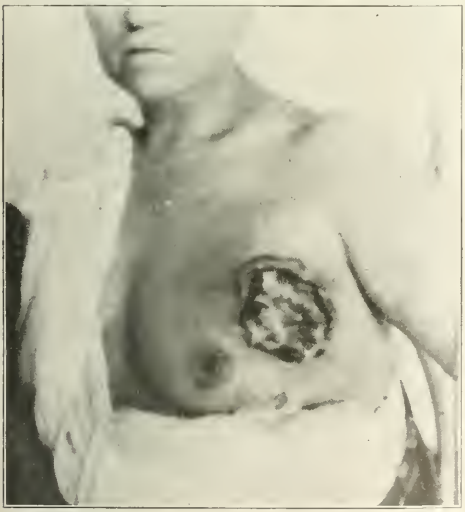

FIG. 1.—Novak. Inoperable medullary carcinoma of the left breast.

be prompt to profit by the remarks of my colleagues to that effect.

My chemical operation is an example of the evolution of scientific therapeutics from an empirical substratum. The use of caustics in cancer is as old as the use of the knife, and the two were for many centuries active competitors. This truth holds good in fact up to the middle of the nineteenth

FIG. 2.—Morey. Inoperable scirrhus cancer of the right breast.

century. Did the use of caustics then fall off from any inferiority of the method as compared with the knife? No. This change came about purely as a result of the introduction into surgery of the use of ether and chloroform anesthesia, which gave the knife an apparent advantage. The use of caustics then remained in the hands of the charlatans for decades, with the exception of the limited utilization of caustic applications like Marsden's paste. In the meantime knife technic has reached a high degree of development, and if every cancer of the breast could be seen and excised at the earliest moment there might be but a very limited field for non-cutting methods. We know, however, that thousands of cases never come to the knife for one or another reason, and that local recurrence in well established cases is the rule even with the most skilful and experienced operators, to say nothing of axillary and internal metastases, coincident thereto.

Let us now glance for a moment at the caustic extirpation of the cancerous breast as it was early in the nineteenth century. The technical defects of the caustic method of that period were both numer-

*Read at a meeting of the Surgical Section of the New York Academy of Medicine, May 3, 1918.

ous and obvious, yet no one seems to have sought to remove them or to keep abreast of the advance in knife technic. Even after the work of Canquoin (1838), who applied zinc chloride in his cases at intervals over a period of four or five months, and did not undertake to proceed against the axillary glands, the method continued to be tedious, painful, and generally imperfect. It was, however, asserted that caustics gave better end results than cutting, which seems easy to understand since some of the greatest surgeons of the time frankly admitted that they never obtain or saw a cure of cancer by the knife, and even in our own time the difficulties of obtaining operative cures in cancer of the breast were voiced by the late Dr. Murphy, who proclaimed that cancer of the breast in a woman in the prime of life was little short of a death warrant.

If the application of the caustic can be deprived of pain; if the lower axillary regional metastases

Fig. 3.—Hutter. Inoperable scirrhus carcinoma of right breast shows grafted surface, following the chemical operation.

can also be successfully and safely removed by caustics, should not this method be considered worthy of an extended trial? If it can be applied equally well to that class of breast cancers called inoperable; if it can be resorted to with safety at any age or stage; if it is known that local recurrence is far less frequent than after the knife; if the resulting operative field is more free from scars and skin tension; if the method is free from the objection of mechanical dissemination; if as a result of its use there would be far less probability of inoculation metastasis, the intrinsic value of the method would, I think, be readily conceded.

If the writer did not believe that he had overcome all these technical difficulties of the chemical operation, he would not feel justified in bringing the subject before your attention. Thus far the operation has been employed almost entirely in the inoperable conditions. A direct result of the caustic is the production of a severe inflammatory reaction followed by a profuse leucocytosis in the tissues underlying and adjacent to the devitalized parts in the floor of the wound, and *in these phenomena resides the intrinsic value of the method, since these processes are theoretically destructive of cancer cells not to be reached by the knife.*

From the year 1867 when Moore suggested the removal by the knife of the axillary lymphatics in operations for cancer of the breast, until the author devised his operation, no one within the profession so far as known has ever given serious thought or scientific effort to the use of caustic for this purpose. The removal, by the use of caustics, of enlarged axillary lymphatics is, however, an established fact, as will be demonstrated.

The disposal of the skin in the cutting operation has always been a problem for the surgeon because of the likelihood of scar recurrence, and it will be recalled that Gross frequently sacrificed the integument outright and allowed the operation wound to heal by granulation. The modernized chemical or caustic operation of the author invariable sacrifices the integument outright, and eventually covers the operated area with skin grafts.

This operation is claimed to be painless, thorough, and safe, in any condition or stage, and gives ideal functional results.

The theoretical value of the method lies in the fact that mechanical dissemination of the disease is rendered improbable. The practical value of the procedure lies in the safe, rapid, and thorough removal of hemorrhagic, necrotic, and generally septic masses, from the pressure and absorption of which these patients suffer. There seems to be no other equally adequate resource.

The operation is and will be increasingly popular with women, the majority of whom would choose this more attractive and safer way; which is also equally expeditious with the standard surgical procedures. With scarcely an exception in the class of cases thus far treated by the author not even a palliative knife operation would have been considered.

Regarding statistics of end results in surgery of the cancerous breast, it should not be necessary to insist on the fact that those obtained at the Mayo Clinic, Johns Hospital, etc., are not representative of the results of the men who must treat the majority of these cases. The old three-year cure criterion has ben abandoned because so many recurrences occur in the fourth and fifth years, and a distinguished operator, Dr. Bloodgood, has moved that the test interval be increased to eight years.

But few trustworthy five-year figures are available. Deaver, in his recent work on "Tumors of the Breast," quotes but four sets, including his own. The others are from the Mayo and Johns Hopkins Clinics and the Prague University Clinic. The five-year survivals in the latter were but 21 per cent. The figures at the Mayo Clinic are slightly less than 30 per cent. Deaver's figures are still better, as 34.6 per cent. were free from recurrence after five years. At Johns Hopkins Hospital (Halsted's Clinic) the percentage of five-year survivors has been slowly increasing from 27.27 to 34.48. Willy Meyer's figures are also slightly below 30 per cent. But many able and conscientious oper-

ators cannot show such figures, and Murphy placed the absolute survival as not over 10 per cent., *i.e.* nine out of ten women would eventually die of the disease if they lived long enough.

The unknown quantity in cancer of the breast is

FIG. 4.—Henville. Inoperable scirrhus cancer of the left breast.

metastasis. If not discovered until after operation it naturally injures the operator's statistics. Dr. Murphy's pessimistic attitude was probably due in part to the number of early bone and other metastases encountered by him. We really know very little about the laws of metastasis.

In conclusion I wish to report four cases treated at the New York Skin and Cancer Hospital.

CASE I.—Novak, Austrian, aged 64 years. Admitted to the New York Skin and Cancer Hospital December 4, 1917. Medullary cancer of left breast. First sign 2½ years ago. One year ago ulceration began with discharge of pus and blood. Ulceration extended rapidly, pain and foul discharge becoming more and more intolerable. Arm became swollen and motion limited.

Tumor size of man's fist in the left breast, with a craterous ulcer undermining the entire breast. Large mass of lymph nodes in axilla. *X*-ray shows metastatic lymph nodes in hyla of lungs. Operation December 5, 1917. Axilla uncovered in the general denudation to give access to axillary nodes. Breast and nodes removed and surface ready for grafting three weeks later when erysipelas broke out in the ward. Mrs. N. was the third victim, the disease attacking the axillary border and sweeping all over the body. She was sent to Bellevue Hospital. On her return several weeks later, the wound had mostly closed by cicatrization and the process was allowed to go on, the condition being unfavorable for grafting. The woman is quite well, cicatrization being almost completed, and her arm motion is gradually returning. On Bulkley diet.

CASE II.—Morey, widow, age 67, multipara, weight 185 lbs. Admitted to New York Skin and Cancer Hospital December 10, 1917. First noticed lump the size of a hazelnut in upper outer quadrant of the right breast just above the nipple. For three years it gradually increased to the size of a hen's egg. Four months ago the surface of the tumor began to ulcerate and to bleed easily upon slight exertion. The nipple had by this time begun to draw inward considerably and much uneasiness was felt in the breast, but nothing amounting to actual pain until recently. No loss of weight noted.

Both breasts are large. The left breast is perfectly normal, sloping gradually downward, as in elderly people, its greatest bulk resting over the twelfth rib.

The right breast is well rounded and protuberant, its nipple line being at least 2½ inches higher than that of its mate on the left, this being due to retraction of the entire gland to the chest wall. The surface of the breast is of an angry bluish red color, shading into the black of incrusted blood, over the ulcerated area. The nipple structures are deeply retracted, forming part of the tumor mass.

The breast is generally hard and brawny, yet soft at its periphery. In the upper part is a hard, irregular tumor the size of a hen's egg, which is firmly fixed to the skin and to the chest wall beneath. The skin over this tumor is ulcerated. The axillary glands are slightly enlarged and somewhat tender to pressure, no palpable nodes in either the supra or infra spaces.

Clinical diagnosis: Inoperable Scirrhus Carcinoma of the right breast. Radiograph of chest showed no metastases.

Operation December 11 at 4 P. M. One hour and fifteen minutes before operation an HMC Abbott No. 2 tablet was administered hypodermically. A second tablet was given an hour later and half of a third tablet at one hour and fifteen minutes. The process of denudation was immediately begun without sign of pain by the patient, by painting the condemned area with pure phenol. KOH was then used throughout the remainder of the process, which consisted in removing all the skin layers, nipple structures, and superficial fascia, leaving exposed the large fat lobules enclosing the several sections of the mammary gland. This proceeding occupied forty-five minutes, a gain of fifteen or twenty minutes over previous similar denudations, due to the use of C. P. phenol, which almost instantly destroyed the otherwise resistant cuticle. This process of denudation with KOH would cause most excruciating pain without narcosis, of course, and it is intensely gratifying to witness the perfect repose of a properly conducted twilight sleep; and not only this, but to note how restfully and peacefully the patient sleeps on for hours after the operation without the terrors of after ether and without the shock so trying to the vital organs. This patient slept all night, awoke refreshed

FIG. 5.—Henville. Present condition following chemical removal and skin grafting. Grafted surface level with chest.

and hungry the next morning, and remembered absolutely nothing of what she had passed through except the pinch of the first hypodermic the night before. Also throughout the zinc chloride treatment, or after it, the patient never complained of pain nor took any morphine or other anodyne. From this time on daily

applications of zinc cloride compound and daily removal of the devitalized plaque were continued until the sixth day when the pectoral muscle was reached. An application was made to this surface for 24 hours and this case left to nature to remove this last layer.

At the end of the second week, while the exfoliation

FIG. 6.—Schneider. Inoperable cancer of the breast. Perfectly well three years after the chemical operation.

of the terminal devitalized plaque was progressing most favorably, the patient developed erysipelas of the face from contact with an erysipelatous case discovered in and removed from the ward to Bellevue Hospital a week prior to her attack. Consequently this

FIG. 7.—Knowles. Kodak view of breast before the chemical operation. Inoperable scirrhus carcinoma. It is now one year and four months since the chemical operation and patient is well.

patient was also immediately sent to Bellevue, as infectious diseases are not allowed at the New York Skin and Cancer Hospital. The face became normal in about one week, but at the same time the disease appeared in the right knee and leg. The disease then swept over her back, where its violence was spent. She was returned to the Skin and Cancer Hospital with a great necrotic sloughing ulcer over the sacrum and two abscesses of the right leg; of these complications she finally died, the immediate cause being metastatic pulmonary thrombosis. At no time was the healing of the breast wound interfered with, the breast wound to the last remaining unaffected.

CASE III.—Hutter, German, aged 64 years. Admitted to the New York Skin and Cancer Hospital January 5, 1918. Two years ago she noticed a lump the size of a cherry in the right breast. At a later period other growths appeared, and the nipple became retracted.

The right breast was retracted to a high level. In the upper outer quadrant was an oblong indurated, nodular, irregular, adherent, ulcerated mass the size of a hen's egg. The axilla contained two sensitive nodes the size of almonds. Radiograph of chest was negative.

The chemical operation was begun January 8, 1918. In two and one-half weeks the breast was ready for skin grafting. Patient wishing to postpone this process, it was not done until two weeks later. Patient feels fine and is apparently perfectly well. Placed on Bulkley diet indefinitely as prophylactic. We show this patient fourteen weeks after the operation.

CASE IV.—J. H., aged 45 years, West Indian negress, single. Admitted to the New York Skin and Cancer Hospital March 19, 1918. Had always been well and hard-working. Some years ago she had received a blow on

FIG. 8.—Galloway. Right breast—Alveolar carcinoma. Left breast—Recurrent scirrhus.

the left breast. Tumor first noticed three years ago. Ulceration one year later.

Examination on admission showed the left breast retracted at a much higher level than the right and containing irregular, hard, insensitive tumor masses which were firmly adherent to the chest wall and superjacent skin. The upper outer quadrant was the seat of a chronic open ulcer, involving the entire nipple structures, which were all firmly adherent, fissured, and characteristically painful, with occasional bleeding. In the axilla were two or three hardly perceptible lymph nodes, slightly sensitive to pressure. An *x*-ray picture by Shank showed probable cancerous involvement of the first rib. Diagnosis (clinical): Scirrhus.

The chemical operation was completed in two weeks and the chest wall was clear. Sufficient time was allowed for the wound to cleanse itself, at the end of which period, one week, the operated area was covered with skin graft taken from the thigh of the corresponding side. All the grafts were successful. Axillary lymph nodes not now palpable Dismissed from hospital April 26, 1918.

We show this patient six weeks after the chemical operation was done and three weeks after the skin grafting. The grafts have all taken and healing is completed, but the surface is still somewhat rough and some of the silver leaf used in the dressings is still adherent. This patient is perfectly well.

And now, Mr. Chairman, I beg your further indulgence and that of the section, while I present four cases that have already been reported in a previous communication, but which I trust will prove of sufficient interest from the prognostic standpoint to warrant their intrusion at this particular time. I present these cases because of their absolutely inoperable condition at the time of admission to the hospital, and because of their wonderful survival and present generally healthy condition. Two of the cases were operated upon at the West Side Dispensary Hospital.

CASE V.—Schneider, German, aged 64 years. Admitted June 5, 1915. Examination showed a large indurated, irregular, adherent mass in right breast, the size of a man's fist, with retracted nipple and tense, shining, adherent skin. Large axillary and pectoral nodes. Pathological examination by Ewing showed adenocarcinoma. Operation June 5, 1915. Axilla exposed at the same time of breast denudation with KOH, under morphine hyoscine narcosis. In the course of the following week, while the breast was being removed, the axillary glands were also removed with KOH. Skin grafting followed and Mrs. Schneider made a rapid recovery. There is no evidence of a return and the patient works actively every day. It is now two years and eleven months since the operation. Axilla clear, arm motion perfect, and skin over site of wound freely movable, soft and white.

CASE VI.—Mrs. Knowles, U. S., aged 78 years, admitted to the West Side Dispensary Hospital January 25, 1917. Scirrhus of the left breast for four years. Had been pronounced inoperable two and one-half years before admission and again one year later. The patient had severe characteristic pains and hemorrhages. There was a growth in the upper outer quadrant of the left breast, the size and thickness of the palm of the hand. It was thick, irregular, firmly adherent to the chest wall, ulcerated, and fissured. There were two metastatic nodes, one the size of an English walnut and the other that of a medium pecan nut, one in the axilla. There were no palpable nodes about the clavicle. The operation was completed in two and one half weeks;

FIG. 9.—Memorial Case No. 2, Tricot. Inoperable medullary carcinoma operated by the chemical operation.

skin grafting not successful on account of unruly patient. Wound was allowed to cicatrize. It is now one year and three months since the operation was done and the patient reports herself perfectly well. On account of the difficulty of grafting and the healing in by cicatrization the resulting surface is more distorted, but none the less healthful, as will be seen upon examination.

The remaining two cases were treated at the Memorial Hospital, and also reported in the MEDICAL RECORD of date Aug. 12, 1916.

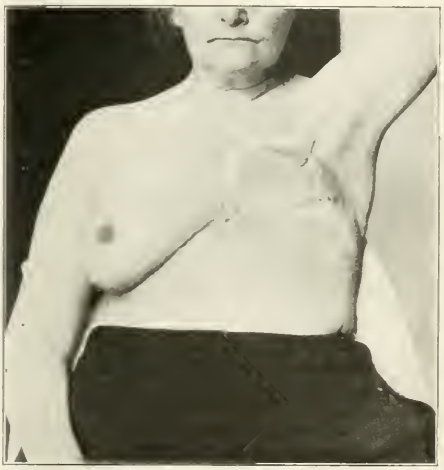

FIG. 10.—Tricot. Two years and eight months after the operation.

CASE VII.—Galloway, Irish, aged 57 years, multipara, admitted August 17, 1915. Bleeding, ulcerative, and suppurating mass, size of hen's egg, in the right breast, and several small recurrent scirrhus nodules in the left breast, following excision two years before. No axillary or enlarged clavicular glands. Pathological diagnosis (Ewing): Alveolar carcinoma; the *x*-ray shows metastasis in the chest (Holding). Operation August 17, 1915. Removed both breasts by chemical method and covered surfaces with skin grafts. Is now perfectly well and robust. We show this patient two years and seven months after the operation. The grafted skin is white, soft, freely movable, and pliable over both breasts. Arm motion is perfect. No axillary nodes to be felt, and *x*-ray picture of chest now shows no change when compared with that taken at the time of operation.

CASE VIII.—October 22, 1915. Mrs Tricot, Irish aged 47 years, multipara. Left breast an immense ulcerating, necrotic, sloughing, and bleeding new growth, with greatly enlarged axillary and supraclavicular nodes. Patient septic and in extremis. Pathological diagnosis by Ewing: Alveolar carcinoma. The *x*-ray showed metastasis in the chest (Holding). Chemical operation October 24, 1915. Axillary nodes cleaned out with KOH. Breast removed in four weeks. Skin graft done later. Convalescence slow. Now seems in robust health. Marched in Liberty Parade down Fifth Avenue one week ago. Breast, axilla, and mediostinum seem free from any sign of the disease.

17 EAST THIRTY-EIGHTH STREET.

Aspects of Life in Germany.—In Bavaria the medical men ask to be consulted in the fixation of rations. According to Professor Oppenheimer, the men of Munich average a loss of 15 per cent. of weight and the women 10 per cent. Contrasted with these figures, the country people lose only 2 to 4 per cent. of weight. While moral factors are in part to blame, there is insufficient carbohydrate, and Oppenheimer wishes more beets grown. Oil is now obtained from the seeds of the linden tree by extraction with benzine. The yield is 11 per cent. Oil is also extracted from the dried hop plant, which also furnishes albumin and aromatic vinegar. Neat's foot oil is restricted for use as torpedo oil, other uses being prohibited.—*La Presse Médicale.*

COMMON DEFORMITIES AND DISABILITIES OF THE FOOT.

By JACOB GROSSMAN, M.D.,

NEW YORK.

CHIEF ORTHOPEDIST, LEBANON HOSPITAL, O.P.D.; CHIEF ORTHOPEDIST, STUYVESANT POLICLINIC; INSTRUCTOR AND ASSISTANT ORTHOPEDIST, NEW YORK POST GRADUATE HOSPITAL AND MEDICAL SCHOOL.

A LARGE number of the deformities and disabilities of the foot are usually the result of wearing poorly fitting foot wear. The shoes are not made to fit the feet, but the feet, in the vast majority of instances, are made to fit the shoes. The result of this mistake is soon evident. The toes become cramped and displaced, the anterior metatarsal arch becomes depressed, crops of corns and callosities appear, the various bursæ and tendon sheaths become inflamed, and finally as a result of weakening of the muscular and ligamentous support of the forepart of the foot, the longitudinal arch becomes relaxed. One rarely sees these conditions in the foot of the laborer. This is so because he wears a broad-toed, commonsense shoe. Women, on the other hand, suffer more often because of the very narrow and pointed shoes that they wear.

For practical purposes the foot can be divided into two parts, the back part, that part behind the mediotarsal joint, and the forepart, that part in front of the mediotarsal joint. The back part is formed by the astragalus and the os calcis and the forepart is formed by the three cuneiform, the cuboid, the scaphoid, and the metatarsus, and the phalanges. While standing the body weight is carried by the back part of the foot; this is more firmly fixed than the forepart. The forepart of the foot is more mobile and gives the spring to the foot in walking. Any abnormality in the structures of the forepart of the foot would result in an interference with the springiness of the foot and subsequent impairment in walking. The most common causes are defects found in the small muscles of the foot, the transverse or longitudinal arches, and the mobility of the toes. Tight, pointed, and narrow shoes weaken the small muscles of the foot, interfere with mobility of the toes, depress the anterior and longitudinal arches; this continued abnormal posture eventually produces disabilities of the foot.

As a base of support the foot is a tripod resting at the center of the heel behind and the heads of the first and fourth and fifth metatarsals in front. The sides forming this triangle are arched. The arches most commonly the seat of trouble are the inner or longitudinal and the anterior or metatarsal arches. The inner or longitudinal arch is high, the height varies in different individuals. It is very susceptible to strain and is often the cause of weak feet. The anterior border of this triangle forms the transverse or metatarsal arch of the foot. Should any of the mechanical elements of the foot be deranged disabilities usually result. The resulting disabilities depend upon the strain about the various joints in the forepart of the foot. The ones that are common are hallux valgus, hallux rigidus, hammer toes, metatarsalgia, and weak feet.

In the hindpart of the foot, the disabilities met with are those resulting from pathological conditions in the bursæ, tendon sheaths, or periosteum. Among the common ailments are tenosynovitis of the Achilles tendon sheath, periostitis of the os calcis, bursitis in the bursæ beneath the tendo Achilles, and spurs on the os calcis.

Hallux valgus is a deformity of the first metatarsophalangeal joint characterized by an outward deflection of the big toe, with, in many instances, an enlargement of the bursal sac forming a bunion. The degree of deflection varies; in some instances it is very mild and is often overlooked; in other instances it is so marked that the big toe lies over or under the second toe.

Hallux valgus results, in the majority of instances, from poorly fitting shoes. In the normal foot the toes are straight, lie flat, and are capable of plantar flexion at the metatarsophalangeal joints. The inner side of the heel, the inner side of the first metatarsophalangeal articulation, and the inner side of the distal end of the great toe lie in a straight line so that in a normal foot a ruler applied to the first two points should come into contact with the inner side of the great toe at its distal end. The conventional shoe is not made to allow this relationship to exist. The inner border of the conventional shoe is not straight as it should be were it made to fit the normal foot properly. It is straight up to a point just behind the metatarsophalangeal joint of the big toe, beyond which it converges abruptly to meet the outer border of the shoe. A normal foot pressed into a shoe of this type will soon assume the same shape as the shoe, with a consequent outward deflection of the first metatarsophalangeal joint of the big toe and an inward deflection of the little toe.

The head of the metatarsal and the base of the proximal phalanx form an angulation, the degree of which varies. In a number of cases the angulation is slight; in others, especially in extreme types, the angular prominence is very marked. The skin overlying the prominence is not affected in the early cases; in the later and more deformed cases the skin becomes inflamed and in some instances the seat of an infection. As a result of the constant irritation and friction by the shoe, a bursa enlarges over the inner part of the capsule of the joint, forming a bunion. Occasionally this bursa communicates with the joint cavity. This bursa or bunion is often the seat of inflammation and in some instances of infection.

The symptomatology is the result of any of the following, either individually or in combination: (*a*) Bursitis, inflammation of the bursa or bunion. (*b*) Traumatic arthritis of the metatarsophalangeal joint of the big toe. (*c*) Tenderness, localized to the area supplied by the digital nerves and resulting from pressure upon these nerves.

The severity of the pain present depends upon the severity of any of the aforementioned processes. Where these are well-marked total disability may result.

In bursitis there are redness, local heat, swelling, and marked tenderness. Occasionally infection occurs and results in a septic bursitis, which may spread to the joint; in such instances the result is a septic arthritis.

Arthritis of the metatarsophalangeal joint manifests itself in pain whenever the joint is moved. The gentlest passive rotation of the toe gives rise to excruciating pain.

Prophylaxis.—Hallux valgus is a preventable de-

formity. People should be educated to wear anatomically correct shoes. They should be impressed with the dangers that may arise from forcing their feet into shoes that are too narrow for them. The writer has observed by actual measurements that

FIG. 1.—Rigid weak foot, right, of gonorrheal origin.

the average foot is one inch wider than the shoe worn by the individual; these shoes are not only too narrow but are one to two sizes too long. These are the reasons that new conventional shoes have to be worn for a while before they are comfortable. During this "breaking-in" period the foot is being forced to assume the shape of the shoe with subsequent cramping and displacement of the toes. Shoes which are anatomically correct are comfortable from the very beginning. They do not require "breaking in," the term commonly used by the patients. A good shoe should have a straight inner border and plenty of toe room so as to allow free action of the small muscles of the forepart of the foot; cramping and displacement of the toes are in this way avoided.

Treatment.—In mild cases, a proper shoe will prevent further deformity. Exercises of the toes may be helpful. In some instances, felt wedges placed between the first and the second toes have proven of some value.

When inflammation is present, the application of ichthyol ointment for a number of days will usually overcome it. During this stage it is well to pad the inflamed area with a piece of felt having a hole in it large enough to surround the bunion. This will protect the sore spot from further irritation of the shoe.

Strapping the toe in such a manner as to straighten it has proven of value in mild cases. A strip of adhesive plaster about one-half an inch wide is placed about the distal end of the toe so that it encircles it about two-thirds of the way, and is carried along the inner border to the dorsum of the foot where it is fastened to the foot by narrower strips of plaster. A second plaster strip can be employed in the same manner so as to reinforce the first one.

In well-marked cases operative interference is indicated. The operation should not be performed while there is any inflammation of the bursa or of the surrounding tissues. It should aim not only to correct the deviation but also to secure free dorsiflexion of the great toe, otherwise the patient will be left with all the disability of hallux rigidus.

In early cases in which there is deformity, but not considerable enlargement, of the head of the metatarsal bone, osteotomy of the head should be performed. In the later stages, where there is marked rotation of the head of the first metatarsal bone, resection of the head preserving the lower or weight-bearing portion should be the operation of choice.

The after care of this condition is important. The splint recommended by Jones is very efficient. It is made of very thin metal. The hole in the splint fits over the inner side of the head of the bone and prevents pressure from occurring at this prominent point. The base of the splint is strapped or bandaged to the inner side of the foot. The toe is then drawn inward and secured to the narrow end of the splint, care being taken that the alignment is correct. Three weeks after the operation the patient may walk, provided he wears a proper shoe. A special bunion shoe, having no seams on the inner side of the last, and made of very soft leather, is best. A metatarsal lift, and a lift of a quarter of an inch on the inner side of the soles and heels, should be inserted. The inner border of the shoe must be straight so as to allow the toe to assume a normal position; abnormal pressure of the shoe on this point tends to reproduce a valgus deformity. The operative area is too tender to permit wearing a shoe until two or three weeks have elapsed. During this time it is best to have the patient reclining, because proper shoes are necessary for obtaining a successful issue.

FIG. 2.—Same case as shown in Fig. 1; the mediotarsal joint in the right foot is ankylosed.

When the wound has healed and the tenderness has subsided the patient, with proper shoes, may then be permitted to walk.

Hammer Toe.—Hammer toe is a deformity of the toe—usually the second, occasionally several—

Fig. 3.—Spastic weak foot; note the eversion of the heels and heel cords.

characterized by flexion of the proximal interphalangeal joint and dorsiflexion of the metatarsophalangeal joint. The prominent knuckle is formed by the interphalangeal joint, and usually is the site of painful corns, the result of friction from the shoe. Corns also develop on the distal end of the last phalanx, the result of friction between the toe and the sole of the shoe.

Hammer toe may be a congenital deformity. These cases are in the minority. The common cause is poorly fitting and tight shoes. Hence it is often associated with hallux valgus and metatarsalgia.

As a rule, the patient seeks relief of the pain resulting from the corns. Occasionally he will seek relief for cosmetic purposes. Total disability is not rare.

Treatment.—The treatment is distinctly operative. The operation of choice, and the one which gives the quickest relief, is one in which a wedge-shaped piece of the interphalangeal joint is removed. A transverse skin incision over the interphalangeal joint is made, and after an oval piece of the skin, including the corn, is removed, a wedge, base upward, including the articular cartilage on both sides of the joint, is removed. Tenotomy of the flexor tendon is then performed. The toe is straightened and the skin is stitched. The toe is fixed to a splint by means of adhesive plaster. The patient is then permitted to get about, wearing the splint in the shoe. The splint is retained for three weeks, when it can be discarded.

Metatarsalgia is a painful disability of the foot due to a flattening of the anterior arch. Pain is characteristic, and is usually localized in the fourth metatarsophalangeal joint, occasionally in the third, and infrequently in the second.

Pain, localized in the fourth metatarsophalangeal joint, and usually of a stabbing or burning character, is the common complaint. When there is a callus on the sole of the foot, pain and a burning sensation are referred to that area. Disability as a result of the deformity is not uncommon.

Tenderness elicited by pressing the offending joint between the finger and the thumb, flattening of the anterior arch, and corns on the sole of the foot, are the characteristic objective symptoms.

Prophylaxis. As this condition is commonly the result of wearing poor shoes, proper shoes, prescribed early, will usually eliminate future metatarsalgia. When there is a tendency to a flattening of the anterior arch, a metatarsal lift of a quarter of an inch should be built in the sole of the shoe. By means of this lift the heads of the metatarsal bones are retained in their proper position.

Exercises properly and conscientiously performed will strengthen the small muscles of the fore part of the foot, and in that way protect it from a metatarsal flattening. The exercises which have proved efficient are: first, grasping motions of the toes, *i.e.* flexion, extension, and spreading of the toes; secondly, lifting objects, such as small marbles, from the floor with the toes; and thirdly, tip-toe exercises.

Treatment.—In mild cases, the treatment outlined above usually gives relief. Occasionally we must resort to pads, in addition. The pads are made of felt, and are applied so that the heads of the affected metatarsal bones are supported in their proper position. They are applied as follows: An oblong piece of felt about a half inch wide and two inches long is placed on the sole of the foot, over the heads or immediately in front of the heads of the metatarsal bones, and retained there by narrow strips of adhesive plaster so placed that they encircle the foot. This pad should be changed twice a week, and continued until relief from the pain has been obtained.

In severer cases, especially where the relief obtained by means of the above measures is partial, a metal support will become necessary. The support which has proved very efficient is the Whitman

Fig. 4.—Same case as shown in Fig. 3.

combination brace. This brace is made upon a model of the foot, made of plaster of Paris. The method of obtaining the plaster cast of the foot is as follows: A towel upon which talcum powder has been dusted is placed upon the floor; the foot

of the patient is well powdered; plaster cream is now prepared and placed upon the towel. The patient then places one foot into the plaster cream, and holds it there while the surgeon molds the cream about the foot. The molded plaster is permitted to set, when the foot is removed. The mold is then well powdered, and filled with plaster cream. When this plaster cream has set the mold is removed, and the cast of the sole of the foot remains. The cast is then properly carved and marked and sent to the brace maker. The metal support is usually constructed of light steel. The anterior extremity of the brace is made nearly as wide as the foot, and extends forward slightly beyond the metatarsophalangeal articulations. The brace also supports the longitudinal arch.

More drastic measures are required in a number of cases, in which, in spite of the above measures, relief cannot be obtained. Operative interference then becomes necessary. Removal of the heads of the offending metatarsals, osteotomy of the second, third, and fourth metatarsals, with correction of the deformity, have been recommended. This should only be done after failure to obtain relief from continued conservative measures.

Fig. 5.—Pes cavus on the right side, weak foot on the left; note the hammer toe (fifth) on the right foot.

Weak Foot.—This condition is a very common one. It has been erroneously called flat foot. There are variations in the types of weak feet, beginning with a slight strain of the ligaments and tendons and terminating with a complete descent of the arch, with osseous deformity. The common picture in the deformity is the abduction and eversion of the fore part of the foot. In early acute cases there usually is tenderness in the region of the inferior calcaneoscaphoid ligament just below the tubercle of the scaphoid, resulting from a strain of this ligament. In these cases, flattening of the arch is never present. It is common in people with high arches. As the strain continues, other ligaments and muscles become stretched, and the tarsus descends, finally terminating in a pes planus. During these stages the pain may be referred to the dorsum of the foot and outer side of the os calcis just below the tip of the external malleolus.

Weak foot is very commonly found in childhood and adolescence. It occurs more often in women than in men. The onset may be acute or gradual, extending over a long period of time. The acute cases may be the result of an inflammatory process, viz., gonorrhea, rheumatism; an injury such as a Potts fracture, or fracture of the tarsus, or the injury caused by a wagon wheel passing over the foot. Most of the cases, however, are of the chronic type. These occur in weakly individuals, and may follow a prolonged attack of an infectious disease, such as grippe, typhoid fever, diphtheria, or pneumonia. Overstrain from prolonged standing or walking will often produce weak feet. Occupation, such as that of policemen, waiters, salespeople, letter carriers, or barkeepers. Finally, obesity and pregnancy associated with overweight may be predisposing factors. The large majority of cases of weak feet are the result of poor footwear. Narrow, pointed shoes with high heels tend to disturb the normal balance, cramp the feet, interfere with the normal action of the muscles and ligaments, and pave the way for weak feet. Any factor which leads to the eversion of the feet throws the body weight on the inner border of the feet and favors the production of weak feet.

For practical purposes, weak feet can be divided into four types, viz.: first, second, and third degree, and rigid weak feet. The early and moderately advanced cases of types 1 and 2 usually show eversion of the heels and heel cords and abduction of the fore part of the foot, with a lowering of the arch as a whole. In the advanced or third type the head of the astragalus becomes partially dislocated inward and downward from the scaphoid, and at times articulates with the latter only at the extreme outer part of the head; in consequence, the cartilage disappears from the portion of the bone that is thus exposed, and the head forms a marked prominence beneath the skin on the inner border of the foot. The arch of the foot gradually diminishes until finally the sole is applied flat to the ground. In well-marked cases the anterior border of the foot becomes abducted, and in very severe cases the inner border of the foot may be convex and the outer concave, so that the patient walks more on the inner side of the foot than on the outer. In very severe cases the peronei tendons may be dislocated from their groove and lie upon or anterior to the external malleolus. In cases of long standing, marked changes also occur in the bones; the uncovered portion of the head of the astragalus becomes enlarged, so that it cannot be replaced in position. Sometimes actual bony ankylosis may take place. There may be effusion in the sheaths behind the tendons and in the tarsal joints.

The symptoms of weak feet rarely depend upon the amount of deformity present; patients with a slight eversion of the heels and heel cords may suffer severely, while on the other hand those with a severe pes planus may suffer very little.

Subjective Symptoms.—(*a*) Pain, present in the majority of cases, usually varies from a severe, cramplike shooting pain to a dull ache. In a number of cases the pain is referred to the back, hip, thighs and calves; it may be unilateral or bilateral; some cases, where both feet are weak, patients may complain of unilateral pain. This symptom is usually more marked late in the day, after the patient has been on his feet; it disappears at rest, and reappears when walking or standing again. At times one sees cases where the pain is usually local-

ized to the outer side of the ankle; this can be accounted for by the pressure of the os calcis against the external malleolus, which occurs from the repeated eversion of the foot, resulting in a localized periostitis.

(*b*) Another symptom which occurs quite frequently is weakness, with discomfort and a tired sensation, present after prolonged standing or walking, usually the result of muscle strain.

(*c*) Many patients complain of numbness and coldness in the feet. This can be accounted for by the impairment of the circulation, which is commonly associated with weak feet.

(*d*) Limp or staggering gait, or stiffness of the knees, especially noticed after sitting, or on rising in the morning, is an occasional complaint.

(*e*) As a result of these symptoms there may be mental depression and nervous manifestations.

Objective Symptoms.—(*a*) The most constant, one can almost say the diagnostic sign of weak foot, is eversion of the heels and heel cords. This varies from a very slight to a very marked degree. The only cases which fail to show this sign are those so-called foot strains. These can practically be disregarded, as they are of infrequent occurrence. To determine the amount of eversion present the patient should stand with his back to the surgeon, who detects the deviation of the heels and heel cords away from the midline of the body. Another method is to recognize the degree of displacement of the anterior tibial line to the inside of its normal position.

(*b*) Some cases are accompanied by a swelling at the outer side of the ankle, in the region of the external malleolus. This is especially evident in fleshy individuals.

(*c*) Muscular spasm or rigidity is very common in the advanced cases. The spasm is the result of shortened and contracted muscles on the outer and upper surface of the feet, due to the persistent attitude of valgus.

(*d*) Limitation of the range of motion is one of the earliest signs of weak feet. The range of motion varies normally, being greater in childhood than in adults, greater in the slender than in the fleshy foot, and greater in the foot used properly than in the one that is not. Normally, the foot can be flexed from 10° to 20° less than the right angle, and can be extended from 40° to 50° beyond the right angle, the range of motion being from 50° to 60°. Passively, the range of dorsiflexion is about 5° to 10° beyond that of active flexion; extension is about the same as active extension; adduction is considerably beyond that of active adduction. Feet which cannot be moved within these limits are said to have limitation of their range of motion. The limitation is caused by the changes in the structure in accommodation to functional use. These changes are at first evident in the muscles and ligaments and later in the articular surfaces of the bone.

In considering the therapy of weak feet we usually group the cases into acute and chronic.

Treatment of Acute Cases.—(1) We attempt to arrest the inflammatory condition which is the primary cause of the affection. In the gonorrheal cases, treatment of the urethra should be instituted. This usually consists of local irrigations and vaccine therapy. One must always bear in mind the great tendency to the occurrence of ankylosis after gonorrheal arthritis, hence immobilization should be employed with caution and for short periods only. Massage and passive movements should be instituted as soon as the inflammatory process subsides. Adhesions in and about the tarsal joints must be broken down as a preliminary measure.

In articular rheumatism a thorough course in salicylates should be administered. Locally, hot fomentations usually offer relief.

In traumatic weak feet, proper correction of the deformity and retention with the feet in marked varus will usually overcome any subsequent valgus deformity.

(2) Rest in bed, with the knee bent and the leg resting upon the outer side, are absolutely essential for the comfort of these patients. Standing and weight bearing should be absolutely prohibited.

As soon as the pain subsides the patient, with proper supports, can leave his bed. The subsequent treatment of these cases is similar to that employed in the early cases of the chronic type.

Treatment of Chronic Cases.—In these patients the onset is gradual, and the symptoms usually are present for a long time. We observe four types of these cases, first, second, third degrees, and the rigid type.

1. The first, second, and third degrees may either be non-spastic or spastic. In the former, passive motion is painless, and free to the normal limit. The treatment of these patients consists of exercises which tend to improve the muscle strength. The following exercises have proved very efficient:

(*a*) Tiptoe exercise: The patient places the limbs in the attitude of moderate inward rotation, raises the body on the toes to the extreme limit, the limbs being fully extended at the knees, then sinks slowly, resting the weight on the outer borders of the feet in marked varus. This should be repeated about twenty or thirty times.

(*b*) Knees extended, the lower extremities should be alternately rotated inward and outward. In this exercise the knees should be held rigid, all the movement occurring at the hips. The object is to strengthen the internal rotators of the hips.

(*c*) Bicycling is an excellent exercise, and should be highly recommended for weak feet.

These exercises should be practised twice daily, and should not be carried to the extent of tiring the patient.

Proper Footwear. To obtain a successful issue in these conditions great stress should be made upon the selection of proper orthopedic footwear. Proper shoes relieve the strain and allow free muscle action. A good shoe should have a broad sole, square low heel, a rounded toe, a straight last, and a lift of a quarter or an eighth of an inch on the inner side of the soles and the heels.

As a rule, this treatment is all that is required in this group of cases. Where the patient is unable to prevent deformity voluntarily a support is necessary to hold the foot in proper position and to relieve the discomfort. In selecting a support for weak feet one should remember the nature of the deformity; that is, acquired weak foot is not a direct breaking down of the arch, but a lateral deviation and sinking. Thus a support, to be efficient,

must hold the foot laterally as well as support the arch. The support which has proved to be very efficient is the Whitman brace. This brace should never be applied to a deformed foot or a foot which is rigid, because the foot cannot adapt itself to the support; spasm and rigidity should first be relieved.

The brace is modeled upon a plaster cast of the foot taken while the foot is held in the fully corrected position. It fits the arch of the foot accurately, extending forward almost to the balls of the toes, outward around the outer border of the foot, and backward to just in front of the tuberosity of the os calcis. On the inner side it is enlarged upward, and extends well on the inner side of the foot. With a properly made support the weight of the foot is not borne upon the apparatus until the arch begins to sink; the foot rests on its normal bases of support, namely, the under surfaces of the heads of the metatarsal bones and the tuberosities of the os calcis. The braces should be accurately fitted and each should be especially made for the individual who has to wear it.

We have at our disposal two methods of taking the cast of the foot. One is taken as follows: The patient is seated in a chair; in front of him is placed another one, somewhat less in height, on which is placed a thick pad of cotton batting or a pillow. This batting or pillow is covered with a towel on which talcum powder has been sprinkled, and the foot of the patient is also dusted with talcum powder. A quart of cold water is then placed in a basin, and plaster of Paris is sprinkled on its surface until it does not sink to the bottom; then it is stirred. When the mixture is of the consistency of very thick cream it is poured upon the towel. The patient's knee is then flexed and the outer side of the foot is allowed to sink into the plaster, the borders of the towel being raised, while the plaster is pressed against the foot until more than half is covered. The foot should be at a right angle to the leg, corresponding to its usual position in the shoe; that is, slightly plantar flexed, and the sole should be in the plane perpendicular to the seat of the chair. As soon as the plaster is hard the upper surface is sprinkled with talcum powder and the remainder of the foot is covered with plaster. The two halves are then removed, dusted with powder, bound together and filled with plaster cream. A little later the outer shell may be removed, and one has a reproduction of the foot. If properly made, this reproduction should stand upright without inclination to one side or the other. If the outer border of the cast is flattened by pressure a little plaster should be added to approximate the normal rounded contour of the foot.

The second method is as follows: The patient sits upon a chair, with his foot upon a second chair of the same height. On this chair is placed a small cushion, with a towel on which talcum powder has been sprinkled. Plaster of Paris is then mixed with water to form a thick cream; a piece of gauze is steeped in the plaster cream and laid upon the towel, underneath the foot, so that the outer border of the sole rests upon it along a line about an inch from the edge. The foot rests on its outer border, and is held at right angles to the leg. The gauze is then wrapped around the foot, covering in the heel behind and extending as far forward as the cleft between the toes; it should reach up just above the internal malleolus, but should not overlap the dorsal surface to any extent. This covering is allowed to set, and when the plaster is hard there is no difficulty in removing the foot from it. A fresh plaster cream is now made, the mold is well powdered, and the plaster cream is poured in it and arranged so that it fills the mold but does not project beyond it in any direction. When the plaster has set, the sides of the mold are forced out and the cast is removed, and marked for the instrument maker.

The brace is made of thin steel or aluminum alloy, and should extend forward to the line of the metatarsophalangeal joint of the great toe and backward to the center of the heel; on the inner side of the foot it extends upward to one-half inch below the internal malleolus, and on the outer side it grasps the foot behind the prominence formed by the fifth metatarsal bone. It should be made to fit the cast accurately, except over the heel, where it should be slightly flattened so as to make it steadier.

A poorly fitting apparatus extends either too far forward or too far backward, and causes much pain, so that the patient is unable to wear it; where it fits properly, however, the patient soon becomes accustomed to it and cannot do without it. It should be worn for short periods at first, the length of time being gradually increased as tolerance is established.

The length of time the support is necessary varies with the condition of the patient and the strain to which the feet are subjected. The brace should be corrected from time to time so as to conform with the changes taking place under its use.

An erroneous idea prevails that wearing of the braces results in an atrophy of the muscles of the foot in consequence of the prolonged pressure. We have failed to find this atrophy in patients that have been under our observation.

Where there is muscular spasm or slight rigidity, where passive motion is painful, and not free to the normal limit, the employment of (1) stretching, either manually or by means of machinery, and (2) strapping usually offers a good deal of relief, and assists in overcoming the spasticity. Stretching should be practised gradually and not too vigorously at first.

Strapping is of special service where the symptoms are acute. The following method has proved to be very efficient: One end of a strip of adhesive plaster about twelve inches long and two inches wide is applied to the outer side of the ankle, just below the external malleolus; the foot is then adducted as far as possible and the plaster is drawn tightly beneath the sole up the inner side of the arch and the leg; it is retained in this position by one or two plaster strips about the calf. Narrow strips are then applied about the arch and ankle in a figure-of-eight manner. Strapping should be done twice a week and continued until the spasm and slight rigidity have been overcome. When this has been accomplished the brace and proper shoes should be recommended.

Treatment of Rigid Weak Foot.—Where there is marked rigidity and deformity, forcible overcorrection under anesthesia is the best method of treatment at our disposal. In this type of weak

foot the foot is held rigidly in the deformed position by muscular spasm and by secondary changes in its structure. The deformity is usually one in which there is a dislocation of the astragalus downward and inward into a position of valgus, the remainder of the foot being turned outward.

The patient should be placed under an anesthetic; the foot is then manipulated in all directions so as to break down any adhesions that may be present. The inner side of the foot should be fixed, and the abduction of the front half of the foot forcibly corrected. This often calls for exercise of considerable force. After this has been done the foot should be put up in plaster of Paris bandages, with the deformity overcorrected. It is well to renew the plaster of Paris bandages every ten days, as they are apt to become loose. In these intervals massage and passive movements in all directions should be practised. The plaster bandages should be retained for about four weeks, when they are to be removed and measurements for a pair of braces taken. The bandages should be reapplied until the braces are ready, when they can be dispensed with. Systematic manipulation should then follow until passive motion is free and painless. This is usually accomplished within a month.

When the parts cannot be brought into position by forcible manipulation, when the bony deformity is extreme, and pain and disability severe, some form of operative procedure becomes necessary. The common operations performed are:

(*a*) Excision of the head of the astragalus. This has proved satisfactory in some cases.

(*b*) The production of bony ankylosis between the scaphoid and the astragalus improves the condition of some patients.

(*c*) The removal of a wedge-shaped portion of the tarsus, the base of the wedge being on the inner side of the foot and the apex at the outer, has proved useful in some cases.

(*d*) Achillotomy, followed by proper after measures, has been done in those cases in which the tendo Achillis was found to be contracted.

Painful Conditions about the Heel.—The common conditions about the heels are tenosynovitis of the various muscles, bursitis, periostitis, and ostetis of the os calcis, the result of injury or inflammation.

Tenosynovitis.—The tendo Achillis is commonly involved, although not infrequently tenosynovitis of the tibialis anticus and posticus is encountered. Pain is marked, and localized in the back of the heel in the former and in the inner side and behind in the latter. The pain is relieved by rest and aggravated by exercise and walking. Swelling due to the effusion in the tendon sheath is both visible and palpable.

The treatment of this condition is primarily rest. Firm bandaging by means of flannel bandages or adhesive plaster, with recumbency during the acute stage, usually suffice in alleviating the pain. After the acute stage has subsided the patient may be permitted to walk, provided the heel of the shoe on the affected side is raised about one-half an inch; this relaxes the tendon and diminishes the strain on it.

Bursitis.—The bursa commonly involved is the one located under the insertion of the tendo Achillis into the os calcis. The pain and swelling are localized to the area of the bursa. The treatment does not differ materially from that of tenosynovitis, hence repetition is unnecessary.

Spurs on the Under Surface of the Os Calcis.—Normally, in *x*-ray pictures, spurs of bone may be seen on the under surface of the os calcis running forward into the plantar fascia or small muscles of the sole. In the majority of individuals they produce no symptoms. Occasionally, especially when injured, a periostitis or adventitious bursitis may result. In consequence of this a painful heel develops, especially evident when walking is attempted.

The treatment at first consists of protecting the heel with a felt heel pad having a hole cut out in the center. When this does not suffice operative interference becomes necessary. The incision should be along the side of the foot and the spur, the tissue around it, and any inflamed periosteum should be gouged away.

Summary and Conclusions.—1. Poorly fitting, conventional shoes produce the majority of acquired foot deformities.

2. Preventive measures will in a large number of instances obviate permanent crippling and suffering. Good orthopedic shoes will usually accomplish this.

3. Early recognition of hallux valgus, metatarsalgia, and weak foot will often shorten the period of treatment and simplify the method used.

4. Conservative measures should at first be instituted before adopting the radical operative measures.

5. Were the medical profession at large to pay more attention to these chronic foot ailments and disabilities, fewer patients would be forced to seek advice from chiropodists and others for conditions which require medical attention.

THE RESULTS OF THE SCHICK TEST FOR DIPHTHERIA SUSCEPTIBILITY ON FIVE HUNDRED SELECTED CASES.*

By CLARENCE A. JOHNSON, A.B., M.D.,

Los Angeles, Cal.

Attending Pathologist, formerly Resident Pathologist, to Los Angeles County Hospital.

This test has come into prominence again quite recently, on account of epidemics of diphtheria among soldiers at the various cantonments in the

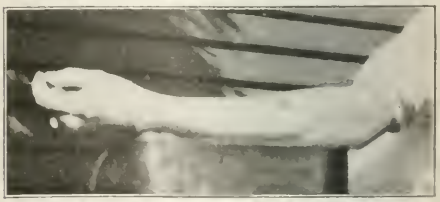

Fig. 1.—A pseudo reaction after 12 hours which disappeared at end of 36 hours in a patient that had received 30,000 units of antitoxin within the week preceding the test

United States, and as those which I made a year ago were on individuals both normal and with in-

fectious diseases, I am taking this opportunity to report my findings.

It might be well at the outset to mention the technique of this test as applied at the present time. The diphtheria toxin is used by injecting

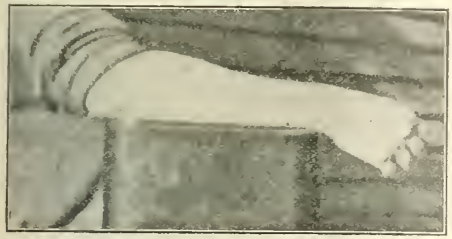

Fig. 2.—No reaction after 24 hours, which became positive after 72 hours, as illustrated in Fig. 3.

intradermically, the dose being one-fiftieth of a minimal lethal dose. For the control the other arm should be used with 50 per cent. more of the diphtheria toxin, which has been heated to 75 deg. in order to kill the thermolabile qualities of the substance. This toxin can be secured from any of the reliable biological chemistry firms.

We will consider the cases for the test under four headings: (1) Those cases which have never had diphtheria, nor have taken prophylactic doses of diphtheria antitoxin. (2) Those cases that have had diphtheria or those which have had immunizing doses of the antitoxin, three or more years previous. (3) Those cases which present symptoms of the disease at the time of the test, or having taken 1000 to 30,000 units of antitoxin within two weeks of the test. (4) Those cases over the age of 21 years which have not had immunizing doses of the antitoxin, and are more or less in danger from exposure.

1. Taking up the cases which have never had treatment or the disease, we shall find that a large percentage will give a positive reaction and very likely at the end of twelve to twenty-four hours. This reaction appears as a reddish area varying in size from a split pea to a dime, or even becomes the size of the palm of the hand within the next forty-eight hours; at the end of seventy-two hours after the injection, the reaction begins to subside,

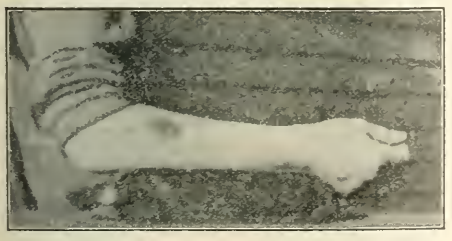

Fig. 3.—Positive reaction after 72 hours.

and, as a rule, the redness will have disappeared at the end of the tenth day, leaving a brown or dark gray color at the site of injection. The control arm of these individuals will frequently show a pseudoreaction. By a pseudoreaction I mean one which appears at the end of twelve hours as a small red area surrounded by a white halo and this incased in a pale pink band. This reaction will quickly disappear and will be entirely gone at the end of thirty-six hours. This must be taken into consideration on reading the test, as individuals who are not susceptible to the disease will frequently show this reaction on both arms. Thus the reason for using both and destroying the thermolabile substance for the control arm.

Table I—Results in 91 Persons Under 21 Years of Age, Not Having Had Diphtheria Nor any Antitoxin.

Age.	Cases.	Pos.	Neg.	Pseudo-Reaction	Per Cent. Pos
Under 6 mo.	3	2	1		$66\frac{2}{3}$
6 mos.-1 yr., inc.	6	5	1		$83\frac{1}{3}$

12 yr.-21 yr., inc	47	12	33 *5	2	26
Total.	94	36 4 5	56 7	2	..

*Eleven cases having scarlet fever at the time the test was applied.
†Five cases all in the same family.

2. The second class of cases includes those which have had the disease, or have had immunizing doses of antitoxin three or more years previously. In this class one quite frequently obtains a reaction on the

Fig. 4.—Positive reaction evidenced at end of 24 hours.

test arm and a pseudoreaction on the control arm. If the individual has within his tissues an immune substance to diphtheria, having been developed during his infection, then both the test and the control will rapidly disappear, and quite frequently show the pseudoreaction that we very often get on the control arm of individuals susceptible to the disease.

The question as to how long an immunity will last in an individual can thus be ascertained, and will vary from two weeks to a lifetime.

Table II—Test Applied to 11 Individuals Having Had Diphtheria or Antitoxin Three or More Years Previous.

Age.	Cases.	Pos.	Neg.	Pseudo-Reactioo	Per Cent. Pos.
8-12 yrs., incl.	2	1*	1	.	50
12-21 yrs., inc.	9	4	4	1	$44\frac{2}{5}$
Total.	11	5	5	1	..

*One case scarlet fever at the time the test was applied.

3. Those cases having the disease or having had antitoxin within two weeks of the test. Under this division we have the means of ascertaining whether our dose of antitoxin has been great enough to produce antibodies in sufficient quantities to overcome the infection or to prevent the disease.

This division will give us the index for those individuals who carry the Klebs-Loeffler bacilli in their throat, but present no symptoms and clear up with local treatment, thus showing that they are immune to the disease and it will not be necessary

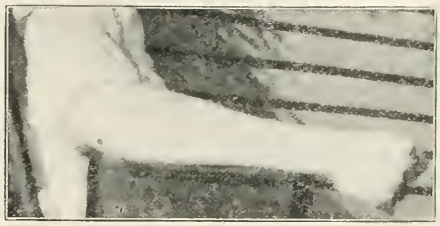

Fig. 5.—Positive after 72 hours.

to administer an antitoxin. And, by applying this test, the problem will be solved why one patient recovers without antitoxin while the next, apparently an exact counterpart, dies in spite of the use of antitoxin.

Table III—28 Individuals Having the Disease or Having Taken Antitoxin Within Two Weeks of the Test; the Amount of Antitoxin Varying from 1,000 to 30,000 Units.

8-12 yrs., inc....	17	1*	15	1	5
12-21 yrs., inc....	6	1**	5	.	$16\frac{2}{3}$
Total.....	28	2	25	1	..

*One case scarlet fever.
**Diphtheria 7 months ago.

4. This class of individuals embraces those who are subject to exposure to diphtheria, such as doctors, nurses, and fellow associates.

This fourth division is probably the most valuable from an economic standpoint, as has been shown by Dr. Abraham Zingler of the M.R.C., who has tested out over 2500 men in the National Army with the result of an average of about 18 per cent. positives. His observations would prove that it is unnecessary to give prophylactic doses to all members of a cantonment in case of a diphtheria epidemic, thus saving the government many thousand

Fig. 6.—The greatest reaction 1 obtained, after 96 hours. Blebs present.

dollars for antitoxin, as well as avoiding much needless pain and annoyance to patients, and the possibility of anaphylactic shock is greatly minimized.

Dr. A. J. M. Treacy of Philadelphia gives the following points for every physician to bear in mind about anaphylaxis: (1) Individuals without any reason to suspect it, may have a hypersensitiveness to antitoxin. (2) Anaphylaxis may appear after an amount of antitoxin given either for immunization or curative effect. (3) It is very likely to happen when a person is given an immunizing dose, then later develops diphtheria and is given more antitoxing. (4) Persons who are of asthmatic tendency or in whom other pulmonary conditions exist, are prone to develop anaphylaxis. (5) All persons who are associated with cattle or horses, as stablemen, farmers, etc., are very liable to show anaphylaxis.

As the tables in this article will indicate, the persons most susceptible to diphtheria and who, therefore, will give a positive Schick reaction, are those between the ages of one to six years, Table 1.

It is a striking peculiarity that members of the same family under 12 will likely give a similar reaction to this test; that is, if a child of two gives a positive reaction, several brothers and sisters in the same family will probably give the same reaction if they have not had the disease or any immunizing doses. This is illustrated in Table No. 1,

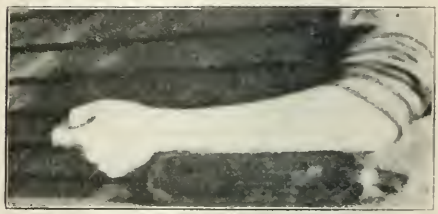

Fig. 7.—A pseudo reaction on an individual that had never had diphtheria nor any antitoxin.

showing a family of five children all under the age of twelve.

Table IV.—Test Applied to 367 Individuals, Such as Doctors, Nurses, and Hospital Employees, Without the History of Having Had Diphtheria.

Age.	Cases.	Pos.	Neg.	Pseudo-Reaction	Per Cent Pos.
Over 12 years.....	367	44	264	59	12

I have been unable to secure any data with reference to children under the age of six months, but in reviewing the literature I find that children not susceptible at the time of birth become so later. The mortality from diphtheria greatly increases at the age of six to nine months, being greatest at nine months; from this age up to the second year, laryngeal diphtheria is especially frequent, and all children suspected of this disease should be given antitoxin at once, and not wait for the application of the test under discussion.

The Interpretation.—A positive reaction, which indicates the absence of antitoxin in the blood, appears in about twenty-four hours after the injection, as a circumscribed redness and slight swelling at the point of application. It continues for a week or more and leaves a brownish pigmentation with superficial scaling for some time after this.

In a small percentage of older children and adults there is a pseudoreaction, even when large amounts of antitoxin are present in the individual.

and these must be carefully distinguished from the true reactions. These are characterized by appearing earlier, being less sharply defined, having greater infiltration, disappearing earlier, and leaving no scale. The question of sensitive skins is shown in Table 1, of scarlet fever.

Referring to Table No. 3, we find that about 22 per cent. give a positive reaction, which gives us an index to individuals who are under treatment but are not entirely immunized, thus informing us that more antitoxin is necessary to protect them from further infection.

Conclusion.—1. This test will tell us definitely who are susceptible to diphtheria, and when an epidemic is threatening we will need to immunize those and those only, disregarding entirely the ones who give a negative reaction.

2. It will be of great economic value to institutions and to nations in time of mobilization of armies.

3. It will greatly reduce the danger of anaphylaxis.

4. As is shown in Table No. 3, the test will be of great advantage in determining the efficiency of immunization by antitoxin, as well as the natural immunity existing in many persons, or the immunity produced after an attack of diphtheria.

600 Merritt Building.

THE CONTROL OF HEMORRHAGE IN VAGINAL HYSTERECTOMY.

By HOWARD CRUTCHER, M.D.,

TULAROSA, NEW MEXICO.

Free access to the broad ligaments having been obtained through preliminary incision and dissection, the great variations in these structures, not only as to mechanical dimensions but as to their essential character, must be borne well in mind. A broad ligament comparatively thin and reasonably elastic is dealt with along the simplest lines, whereas a thickened ligament of unyielding tissues presents a far graver problem to the operator.

It may be affirmed as fundamental that the

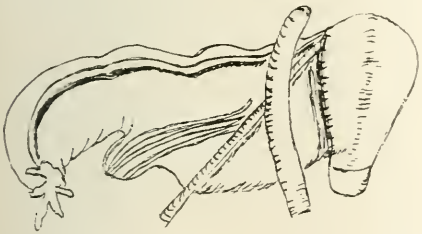

Fig. 1.—Illustrating the complete inclusion of all the tissues of the broad ligament, but not the nearness or remoteness of the blades or the clamp to the walls of the uterus itself. Note how completely the tip of the clamp overlaps all tissues.

nearer the operator clings to the muscular coat of the uterus the less bleeding he will provoke. The uterus may, indeed, be removed under certain highly favorable conditions without the application of either clamps or ligatures, with slight capillary bleeding, but such an operation has nothing whatever to commend it in preference to others in which the broad ligaments are secured through the everyday familiar methods. The uterine artery does not normally penetrate the

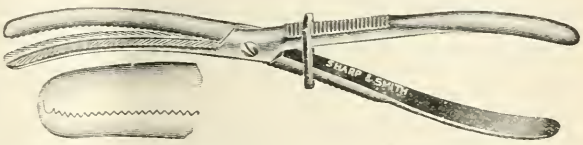

Fig. 2—Hysterectomy clamp.

uterus at any point, but its course is subject to wide variations due to obvious causes, and no cautious operator is ever unprepared to deal promptly with such deviations as he may find in his way.

The fundus of the uterus having been drawn well forward until it is really almost a part of the outer world, the lower blade of a long, strong, thoroughly dependable clamp is pressed below and behind the womb until its point is in evidence at a safe distance beyond the cornu of the organ. All interfering tissues having been cautiously examined and driven from the field, the opposing blade is now pressed evenly and firmly toward its fellow until the operator is certain that the broad ligament, and the broad ligament only, is within the grasp of his instrument. The idea I mean to convey to the reader is very well illustrated in the accompanying illustration (Fig. 1). Just how close to the uterus the clamp shall be applied must depend upon the judgment of the operator, but the immense shrinkage following the division of all large pedicles must be borne well in mind. In a thickened ligament the clamp should be applied so as to insure a very large margin of safety after the uterus has been cut away. The object of the operator in applying the clamp being to compress every blood vessel beyond all possibility of bleeding, the non-vascular tissues of the ligament must be looked upon as so much padding, the presence of which must be provided for as in all other cases of the kind.

In a second illustration (Fig. 2) I present a suggestion for a clamp that appears to me to be almost ideal in its qualities. The blades of the clamp must be long, broad, somewhat elastic, and of strength many times beyond what may be supposed to be the actual necessities of the case. In no case of the kind is it possible to devote too much time and thought to even the minutest detail of the operative work. The blades of the clamp must be long enough to overlap the broad ligament at one grasp; broad, that the tissues may not be cut by its application; and elastic, that no subsequent slipping may be possible through shrinkage of the pedicle. The principle of the tongue-and-groove I believe to be an excellent one in all cases of broad ligament compression, but especially desirable in cases where the tissues are thick and unyielding. I may add that I find no more difficulty in removing them than I have had with other less dependable blades. In all cases of vaginal hysterectomy in which I have applied clamps to the broad ligaments, it has been my invariable rule to remove the instruments after

forty-eight hours, first releasing the locks for a few hours, then withdrawing the blades gently, and in no case have I a secondary hemorrhage to record. In saying this I hope not to be understood as advocating any hard and fast rules for the removal of clamps from the broad ligaments. I have known operators of high skill and excellent reputation to remove their clamps within a much shorter period, but in my own case I have never felt justified in following their practice in this respect. There is of course no fixed rule to guide us in such matters, but so far as my own practice is concerned I would rather leave my clamps more than forty-eight hours than remove them before the expiration of that period. The post-operative complications of vaginal hysterectomy need not be considered here at this time, but it may be stated that they are as a general rule neither numerous or serious.

THE SEWAGE DISPOSAL PROBLEM OF NEW YORK CITY.

A REPORT BY THE PUBLIC HEALTH COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.*

MANHATTAN ISLAND has been called a body of land entirely surrounded by sewage. The condition of the waters, polluted by sewage discharged into them has been a matter of serious concern to the city. In the course of the various studies made of the situation it has been ascertained that some parts of the East and Harlem Rivers become very heavily polluted. At times there is a complete absence of free oxygen in the Harlem River, a condition which is to be observed particularly during or just following the hot summer months. Considerations of public health, navigation, and decency demand a proper solution of the problem.

The main body of water of the New York harbor is the Upper Bay, which has a surface of 20.74 square miles, and the average depth of the channel is from 40 to 50 feet. This body of water acts as a huge equalizing reservoir for the upland and tidal flows. The upland flow entering from the Hudson River averages about 2,220 million cubic feet per day, and according to the United States Coast and Geodetic Survey that from Newark Bay averages about 203.5 million cubic feet per day. The tidal flow every day brings in about 7 billion cubic feet of water through the East River and Long Island Sound, and 23 billion cubic feet through the Narrows from the lower bay and ocean. The water in the East River oscillates back and forth, due to the differences in elevation between the waters in the bay and in Long Island Sound. Similarly, there is no continuous flow in the Hudson River. Here also the water oscillates back and forth under tidal influence, but unlike the East River there is a marked preponderance toward the ocean due to the fresh water coming down from the north. At times sea water flows up the Hudson almost to Poughkeepsie. This constant oscillation of the water is an element of importance in connection with the digestive capacity of the harbor.

The condition of the harbor due to the existing methods of sewage disposal is very bad at certain points. The United States Government, having oversight of navigation, is constantly calling the attention of the city authorities to the large amount of floating sewage. At times of low tide the conditions are shocking in some parts of the harbor, particularly in the lower East River and the Harlem River where there are a number of sewer outlets discharging into a comparatively small body of water. The water which normally holds in solution free oxygen to the extent of 7 to 10 cubic centimeters per litre, digests a large amount of the sewage, but its assimilative capacity is, of course, limited. At times when the lack of free oxygen makes aerobic action impossible, the anaerobic process sets in and the water turns black and foul odors are emitted. The Passaic River at Newark, the Gowanus Canal in Brooklyn, and the Harlem River at times reach this stage of complete absorption of all free oxygen. Tests made of the water in the Harlem River and East River through a series of years show how rapidly the assimilative oxydizing capacity of these rivers is diminishing:

MINIMUM OBSERVED PERCENTAGES OF SATURATION.

	Harlem River at Morris Heights	East River at 42nd Street
1906	..	95
1909	46	57
1911	40	51
1912	33	59
1913	11	53
1914	6	26
1915	8	25
1916	0	4

Similarly low figures of the oxygen content of these waters have been obtained at other points in the two rivers.

The amount of sewage produced in a city is roughly equal to the consumption of water for all purposes, plus the rain water which finds its way into the sewers. Accordingly it is larger in an industrial than in a rural community. On this basis estimates have been made that a daily average of over 100 gallons of sewage per capita is produced in New York. The city now produces about 600 million gallons of sewage daily and as it continues to grow the amount of sewage will increase at a corresponding, if not at a faster, rate, as the general experience has been that as cities grow the amount of waste per capita increases.

Organic matter in New York City sewage varies greatly. It constitutes from 0.4 to 1.0 per cent. of the sewage effluent and is derived in about equal proportions from animal and vegetable refuse. A part of the organic solids of sewage, when reaching the harbor, sinks to the bottom, a part stays suspended in the water and a part floats on the surface.

*The report was prepared by E. H. Lewinski-Corwin, Ph.D., and approved by the Public Health Committee, the membership of which is as follows: Charles L. Dana, M.D., chairman; James Alexander Miller, M.D., secretary; John S. Billings, M.D., Nathan E. Brill, M.D., Robert J. Carlisle, M.D., Floyd M. Crandall, M.D., Lewis Fox Frissell, M.D., Arpad G. Gerster, M.D., John A. Hartwell, M.D., Thomas W. Hastings, M.D., L. Emmett Holt, M.D., Abraham Jacobi, M.D., Howard Lilienthal, M.D., Walter L. Niles, M.D., Bernard Sachs, M.D., Thomas W. Salmon, M.D., Frederic E. Sondern, M.D., W. Gilman Thompson, M.D., Frederick Tilney, M.D., Philip Van Ingen, M.D., Karl M. Vogel, M.D., George B. Wallace, M.D., Herbert B. Wilcox, M.D.; E. H. Lewinski-Corwin, Ph.D., executive secretary.

There are several ways of preventing harbor pollution by gross organic matter. The sewage can be made to pass through screen chambers at the sewer outfalls and the gross material removed, or the effluent can be put through sedimentation tanks.

It is estimated that a screen plant for 25 million gallons daily will accumulate 12 cubic yards of organic matter a day if the sewage is passed through a fine screen (1 16 inch to 1 8 inch). Sedimentation tanks constitute probaly a more efficient means of sewage purification but require relatively large areas along the water fronts.

In New York, where sewage is discharged without treatment of any kind and where accumulations of sludge are considerable, periodic dredging of the harbor is urged by some as a means of cleaning the harbor, pending the installation of treatment works.

Account of Commissions.—The serious conditions of pollution existing in the harbor have been recognized by the city for a long time and two commissions were appointed, one almost immediately succeeding the other, to study the problem and devise means for meeting it adequately.

The New York Bay Pollution Commission, appointed by the Governor, made its report on March 31, 1905, on the condition of the waters, which was followed by another report made on May 3, 1906. This report brought out several points with regard to the pollution of the harbor waters: First, that there is not a proper dispersion and diffusion of the sewage and that in many instances the sewer outlets produce local nuisances, particularly when the sewage is emptied at the bulkhead rather than at the pierhead lines; second, that if a better method of disposal and treatment of sewage could be provided there is enough free oxygen in the waters to digest it without the production of local nuisances or offensive odors, and third, that the whole subject requires a very thorough study. The Commission recommended that a new commission with ample powers and funds be created in order to make such an intensive study.

Following the exposition of the conditions by the Bay Pollution Commission and its recommendation that some comprehensive method of dealing with the situation be devised, in 1906 the Legislature appointed the Metropolitan Sewerage Commission which, after eight years of study of the problem, submitted its final report in 1914.

Main Recommendation of the Metropolitan Sewerage Commission.—The system recommended was characterized by the Commission in one of its reports as consisting "largely of intercepting conduits to collect the sewage from the local sewerage systems to a number of centrally situated disposal plants where sufficient of the impurities can be removed to permit the effluent to be discharged into the harbor waters without danger or offense. No interference is proposed in regard to the local sewerage systems. The main drainage system would take the sewage from the local sewers and carry it to suitable points for treatment and disposal and would thus relieve the harbor from its present excessive contamination." The system of main drainage which the Commission recommended was presented for adoption by the city both as a plan and a policy for future construction, to be carried out in successive steps and not as one undertaking.

The metropolitan plan provided for intercepting sewers along the upper part of Manhattan and the Harlem shores of the Bronx, leading to a disposal plant on Ward's Island, to have been finished in 1916. Areas tributary to the lower East River in Manhattan and in the congested section of Brooklyn were to have delivered their sewage to independent treatment plants along the waterfront. By 1920 the Harlem and Bronx sewers were to have been extended. In northern Queens intercepting sewers were to have been extended, leading to treatment plants near College Point for Flushing and Cryder's Point for Douglaston, and the Jamaica Bay and Rockaway sewers were to have been well under way. In 1925 the eastern Bronx intercepting sewer was to have been completed, discharging after treatment at Hunt's Point. In that year the connecting up of the sewers of the east side of Manhattan below Twenty-sixth Street and a part of the Brooklyn waterfront from Newtown Creek to about Fulton Street with Ocean Island was to have taken place. In 1930 all of the planned intercepting sewers were to have been finished and several sewers in Richmond were also to have been completed. The total cost of the whole undertaking was to have amounted to $51,469,400.

Criticisms of the Metropolitan Project by the City's Engineers.—The Sewer Plan Commission was appointed by the Board of Estimate and Apportionment and consisted of the consulting engineers of the five boroughs and of the chief engineer of the Board of Estimate and Apportionment. In 1915 its name was changed to the Bureau of Sewer Plan. On January 1, 1916, it was merged with the Bureau of Public Improvements, under the general direction of the chief engineer of the Board of Estimate and Apportionment.

The following are the several points on which the Commission and the city's engineers are in substantial agreement:

1. That the digestive capacity of the harbor for sewage should be utilized as far as is consistent with due regard to public health and welfare.

2. That the system of main drainage and disposal should be built progressively.

3. That the schemes for the disposal of sewage by (*a*) collection at one central location for treatment, (*b*) by treatment upon farming land, (*c*) by disposal at sea at one point, and (*d*) by the establishment of filtration plants within built-up portions of the city, should not be considered.

4. That the sewage which enters the North (Hudson) River from Manhattan and Bronx can be properly treated by screening. Where the Commission and the city engineers disagree concerning this point is as to the type and location of screens.

5. That a rational scheme for sewage disposal in certain parts of the harbor must include intercepting sewers, but they disagree as to the locations indicated by the Metropolitan Commission along the Harlem and lower East Rivers. The ob-

jection to this is that it would cause the discharge of a very large amount of sewage at one point.

The disagreement between the Metropolitan Commission and the city's engineers is of a fundamental nature as it refers to the following five principal matters:

1. Standards of cleanness.
2. The ocean island.
3. The Ward's Island project and the alleged failure of the metropolitan plan to make the maximum use of the digestive capacity of the harbor by more uniform diffusion and distribution of the sewage.
4. The use of fine screens instead of Imhoff sedimentation tanks along the lower East River, and
5. Administration.

1. *Standards of Cleanness.*—In 1912, after having obtained expert advice from specialists in this country and abroad, the Metropolitan Commission adopted for its guidance the following five standards of cleanness which were the "result of much thought, many investigations, and the best expert advice procurable":

(*a*) Garbage, offal, or solid matter recognizable as of sewage origin shall not be visible in any of the harbor waters.

(*b*) Marked discoloration or turbidity, due to sewage or trade wastes, effervescence, oily sleek, odor, or deposits shall not occur except perhaps in the immediate vicinity of sewer outfalls, and then only to such an extent and in such places as may be permitted by the authority having jurisdiction over the sanitary conditions of the harbor.

(*c*) The discharge of sewage shall not materially contribute to the formation of deposits injurious to navigation.

(*d*) Except in the immediate vicinity of docks and piers and sewer outfalls, the dissolved oxygen in the water shall not fall below 3.0 cubic centimeters per litre of water. (With 60 per cent. of sea water and 40 per cent. of land water and at the extreme summer temperature of 80 degrees F., 3.0 cubic centimeters of oxygen per litre corresponds to 58 per cent. of saturation.) Near docks and piers there should always be sufficient oxygen in the water to prevent nuisance from odors.

(*e*) The quality of the water at points suitable for bathing and oyster culture should conform substantially as to bacterial purity to a drinking water standard. It is not practicable to maintain so high a standard in any part of the harbor north of the Narrows, or in the Arthur Kill. In the Lower Bay and elsewhere bathing and the taking of shellfish cannot be considered free from danger of disease within a mile of a sewer outfall.

The city's engineers criticized some of the standards. Standard 2 was criticized because it is not sufficiently definite and because it leaves the determination of what constitutes a nuisance to individual judgment.

Standard 4 was criticized because it required a very high percentage of free oxygen. There exists a great deal of difference of opinion among experts on the subject and it was thought that the percentage of free oxygen required was too high. The city's engineers believe that the dissolved oxygen in some parts of the inner harbor may with safety be allowed to fall at times even below 20 per cent. of saturation. However, they expressed themselves in favor of the dissolved oxygen content test as a part of a standard of cleanness, because they considered it as one of the best known chemical measures of the approach of undesirable conditions. The Metropolitan Commission, despite the fact that at first it formulated the very high oxygen content standard and allowed such a standard to be its guide in formulating sewerage plans, later entirely abandoned this oxygen content part of the standard of cleanness because they believed that the other recommendations, if carried out, would insure the necessary degree of saturation of the water with oxygen. The city's engineers criticiszed this abondonment.

The city's engineers also criticized the fifth standard, considering it unwise to maintain the waters of the harbor in a condition suitable for major fish life. They contend that to maintain the water at such a high level of purity would be undesirable and economically too costly.

2. *The Ocean Island.*—The criticisms against the ocean island are (*a*) that it is very costly and that it may possibly lead in the future to the duplication of the tunnel and island to take care of the sewage from Ward's Island; (*b*) that making proper use of the assimilative capacity of the harbor waters by providing outlets at most suitable places will take care of the sewage without building this costly enterprise; (*c*) that by adopting the ocean island plan the conditions in certain parts of the harbor will be rendered worse than they are at the present time, pending the final construction of the trunk tunnel, for it is planned as a step toward the realization of the ocean island idea that intercepting sewers and enormous screening plants be built on each side of the lower East River and the sewers would discharge in the neighborhood of Corlear's Hook and South Fifth Street, which is one of the most thickly populated portions of the waterfront and where the tidal action as shown by observation of floats is very sluggish.

3. *The Ward's Island Project.*—The building of large treatment works at Ward's Island, whither sewage from a very large area will be brought, is considered a violation of the fundamental principles of sewage disposal, for it does not recognize the advantages of diffusion of sewage throughout the harbor, but concentrates it in a very narrow arm of water which is, in the larger part of it, very shallow and where the tidal action is oscillating. The selection of the place is considered very bad as it is at a maximum distance from any source of clean water. The building of a treatment plant on Ward's Island places it very near to a thickly inhabited portion of the city. This plant would be separated by only 1,500 feet of open space from the population of the neighborhood.

4. *Sedimentation Tanks.*—Without going into a very technical discussion of the advantages and disadvantages of the various forms of screening plants, it may be stated that the city's engineers favor the sedimentation tanks which were spe-

cifically rejected by the Metropolitan Commission. The city's engineers recommend the construction of sedimentation basins underneath marginal streets along the East River where they will not interfere with other structures nor be in too close proximity to dwellings. They believe that the basins can be so designed that they will be unobjectionable and assert that there are large sites available for such sedimentation basins along the lower East River. They stated that there is a good precedent in Germany for constructing such tanks in populous districts without any offense.

5. *Administration.*—The Metropolitan Commission recommended the appointment of a permanent commission to control the construction and administration of the sewerage system of the city. The city's engineers take exception to this recommendation as "there is nothing connected with the construction of the works proposed by the Metropolitan Commission nor in the suggested modifications of them which is so new or strange that it cannot be successfully tried out by the borough authorities who are already engaged in designing and building works of a similar character and in some cases of equal magnitude and difficulty under the direction of the Board of Estimate and Apportionment."

Proposals for Immediate Relief by the Bureau of Public Improvements.—The plan proposed by Mr. Lewis and his bureau for the immediate relief of the harbor consists of three major parts, all of which aim chiefly at cleaning up the Harlem River and parts of the East River. The first part of the plan contemplates the interception of all the sewage now entering the Harlem River from the Bronx at and north of Fordham Road. It is proposed to treat the sewage and to discharge it into the Hudson at a point north of the Spuyten Duyvil Bridge. The point of disposal is claimed to be particularly well suited for the purpose as it affords ample dilution in relatively unpolluted water and it affords available land for sedimentation or screening. The volume which would be discharged there by 1940 is estimated at 22½ million gallons daily.

The second part of the plan provides for the discharge of sewage now tributary to the Harlem River from the Bronx, between New York University (Cedar Avenue) and Park Avenue. The plan is to collect this sewage at Jerome Avenue and to carry it under the Harlem River by an inverted siphon to East 156th Street, and thence combined with the Manhattan sewage entering the Harlem River, between East 190th Street and East 132d Street, through a tunnel under 155th Street to the Hudson River. The sewage now tributary to the Hudson River, between West 145th Street and 162d Street will here combine with the other sewage and the whole will be pumped after treatment through several submerged outlets at points as remote from the pierhead line as practicable. It is proposed that the outlets will discharge about 1,000 feet from shore, where the water has a depth of about 43 feet at low tide. It is estimated that the amount of sewage from the Bronx alone so diverted to the Hudson River will be 40½ million gallons daily in 1940. The cost of carrying out this project, including the tunnel under 155th Street, was estimated at $3,106,000, and the annual cost of upkeep, including interest and depreciation charges, was estimated at $284,000.

It will be observed that these two parts of the plan provide for the transfer of sewage from the East and Harlem rivers to the Hudson River. The chief engineer of the Board of Estimate and Apportionment is of the opinion that, if the sewage is properly screened and if the effluents are discharged from submerged outlets in the channel it will not appreciably pollute the Hudson except perhaps to render the water a little more turbid. The volume of water in the river is very large and the flow toward the sea is more marked than in the other sections of the harbor. On this point, however, there is a difference of opinion. Some of the experts consulted fear that the large sewage discharge might eventually result in overtaxing the digestive capacity of the Hudson, rendering the waterfront unfit for some of the uses to which it is now put. It is claimed that the submerged outfalls will not prevent the occurrence of certain nuisances objectionable to sight, as grease and other substances will come to the surface. It may also detract from the high character of the residential section along the river front.

The fear has also been expressed by some that the precedent thus established by New York City of adding vast amounts of pollution to the Hudson may lead to the abandonment on the part of some of the up-river cities of any restraints they might have adopted in discharging sewage and other refuse into the River. It will also weaken the objections which have been raised by New York to the pollution of the river and harbor by the communities on the New Jersey coast.

The third part of the chief engineer's plan provides for a temporary screening or sedimentation plant at the end of 132nd Street, which will collect the sewage from the southern and eastern parts of the Bronx, now entering the Harlem River, Bronx Kills, and East River, between Third Avenue and Cabot Street. This sewage is now discharged into the harbor under most unfavorable conditions from the Third and Brook Avenue sewers. Eventually it is planned to convey the sewage by a tunnel to a treatment plant on either Ward's or Riker's Islands, or possibly to Sunken Meadow, or to distribute the volume between the two islands. It is estimated that the amount of sewage from this area will be 43 million gallons daily in 1940.

It is further proposed to alleviate the pollution of the lower East River by building a number of tank treatment plants along the waterfront on the Manhattan side in places where the pollution is heaviest. It is claimed that such treatment plants can be operated without offense to the immediate vicinity. Practically all of the sewage entering the East River from Brooklyn will, under the proposed plan, be intercepted and carried to the upper bay. It is also proposed to protect the Hudson shore of the Borough of Manhattan by fine-screening the sewage.

Summary—The present method of sewage disposal

in New York City is inadequate in that: (*a*) The amount of sewage discharged is unrelated to the digestive capacity of the several waterways surrounding the city; (*b*) The sewage is discharged in to the harbor waters without preliminary treatment; (*c*) The sewage is, in many instances, discharged at the bulkhead line instead of further out in the channel where it could be better digested and carried away at a more rapid rate. (*d*) It has made unsafe the utilization of the shore waters for bathing purposes.

II. The excessive sewage pollution of the East River and particularly the Harlem River has made necessary the application of immediate measures of relief. During and following the hot months the available supply of free oxygen in these two branches of the harbor waters may become entirely exhausted and the anaerobic action of the bacteria may create a serious and offensive nuisance. Should this come to pass, it will result in a detriment to the welfare of the immediate neighborhoods and a depreciation in the real estate values with a resultant loss of revenue to the city.

III. The grave condition of the harbor due to sewage pollution has been a subject of official inquiry since 1905, first by the New York Bay Pollution Commission and then by the Metropolitan Sewerage Commission. Exhaustive reports on existing conditions have been prepared and plans for a comprehensive solution of the problem have been worked out.

The plans recommended by the Metropolitan Sewerage Commission, involving the outlay of over $50,000,000 have been criticized by the city's engineers and other experts and plans have been designed by the chief engineer of the Board of Estimate and Apportionment to relieve the pollution where it is heaviest. The value of the substitute plan lies chiefly in the fact that it can be put into operation without unduly straining the financial resources of the municipality, as the city is already within $5,000,000 of its debt limit. Moreover, the plans of the chief engineer of the Board of Estimate and Apportionment constitute a part of a more comprehensive scheme which can be extended should future conditions so require.

Conclusions and Recommendations.—The Public Health Committee has devoted a great deal of time and study to the problem of sewage pollution of the waters around New York City and has held numerous conferences with experts on the subject.

While the Public Health Committee is in favor of having the city deal with the problem in a comprehensive manner, yet we are assured that financial consideration would indefinitely postpone the undertaking of an enterprise involving the expenditure of a vast sum. Moreover, the progressive nature of the science of sanitary engineering and the recent advances made in methods of sewage treatment make it perhaps undesirable to commit the city to any one project, the realization of which is bound to take more than a decade at best.

In view of the fact that the conditions existing in the East and Harlem rivers are such as to require immediate action on the part of New York City, the Public Health Committee recommend that the Board of Estimate and Apportionment adopt, as soon as possible, plans designed to relieve the serious pollution prevailing in these two branches of the harbor waters and make the appropriation of the funds needed for carrying out such plans.

Medicolegal Notes.

Sunstroke, Disease or Violent Personal Injury?—An accident insurance policy provided, "If sunstroke, freezing, or hydrophobia, due in either case to external, violent, or accidental means, shall result, independently of all other causes, in the death of the insured within ninety days from the date of the exposure or infection, the company will pay said principal sum as indemnity for loss of life." The Oklahoma Supreme Court holds that "accidental means" is used to denote "accidental cause," and in case of sunstroke, if the same was suffered while the insured was engaged in his usual avocation or going about his affairs in an ordinary manner as any other person might have been under like or similar circumstances, and did not intentionally and voluntarily subject himself to an intense heat calculated to produce sunstroke, with the knowledge that it would probably occur, then the sunstroke was suffered from "accidental means" or "accidental cause" within the meaning of the policy; that is to say, that "sunstroke," as used in the policy and as understood by the insured, was treated in the nature more of an accident than as a disease. The court said: "While the decisions generally, with a few exceptions, hold that sunstroke is a disease, it is not regarded as a disease in the popular mind. In the common understanding of the insuring public it is accounted a kind of violent personal injury, from the very idea of sudden and external force carried by the word. If classed by medical authorities as technically a disease, to none but an expert medical mind would the provisions of this policy have carried this significance. Particularly is this true, when read in connection with the other two conditions, freezing and hydrophobia, provided for in the same clause of the contract."—Continental Casualty Co. v. Clark, Oklahoma Supreme Court, 173 Pac. 453.

Evidence as to Testamentary Capacity.—In a will contest where one count of the complaint asserted testamentary incapacity there was abundant evidence that at the time of making the will the testatrix was of a sound and disposing mind and memory. It was held that any previous disturbed mental condition shown to have existed some four days earlier as testified by a witness was not evidence contradicting the testimony bearing upon the mental condition of the testatrix at the time of the execution and publication of the will. Such former mental condition was a circumstance which, when supported by other circumstances, might properly be admitted as evidence, but, standing alone, was insufficient to justify an inference that such mental condition continued until the time of making the will, when positive testimony in abundance was to the contrary. —Morrison v. Castillo, Arizona Supreme Court, 173 Pac. 417.

Proof of Medical Services in Personal Injury Actions. —The Illinois Appellate Court holds that as medical services are capable of definite proof, if recovery is sought therefor in an action for damages for personal injuries, such proof must be made, and the jury have no right to assess such damages simply from their own knowledge, observation and experience in the affairs of life.—Harrold v. Clinton Gas & Electric Co., 205 Ill. App. 12.

Expert Opinion as to "Reasonable Probability" of Future Suffering.—The Washington Supreme Court holds that the admission of expert testimony that the plaintiff in an action for personal injuries would suffer specified ailments in the future as a result of her injuries with "reasonable probability" was held proper upon the question of the amount of damages; "reasonable probability" not differing materially from "reasonable certainty."—Holt v. School Dist., Washington Supreme Court, 173 Pac. 335.

Military Medicine.

PATHOGENESIS OF WOUNDS OF THE EXTERNAL GENITALS IN WARFARE.

WHAT strikes one in looking over the records of these injuries is the difference offered by the lesions relative to their manner of production, their site, and the lesions which accompany them. Although there are cases where the scrotum alone was involved, these injuries are more often combined with more or less severe disorders of some neighboring organ. Given the great variety of modern missiles the resulting injuries are likewise varied, but the most important factor is unquestionably the momentum and shape of the vulnerating agent. For the same reason there is no need of making a difference between wounds resulting from an exploding shell and those due to bullets.

During the first six months or so of the war bullet wounds were very common, and in May, 1915, Cathelin in his report on the Urological Center at Orleans, noted that a great number of wounds that were being treated there dated back to the battles in Belgium and the Marne, and he explained this by the fact that in the early part of the war the Germans aimed low. There are two other reasons of this frequency, the first being the greater penetrating force of modern missiles whether bullets or bits of shell. From their anatomical situation, the scrotum and testicles are fairly well protected from external violence, above by the pubis, on the sides by the upper part of the thighs, and they are only directly accessible to missiles when these strike from in front or when they strike tangentally on the perineum. Then again, the mobility of these organs often saves them from traumatism, so that it can be readily conceived that modern missiles, endowed with a very considerable penetrating force, may involve the scrotum and its contents after having passed through a thick muscular mass. The second reason which may also explain the relative frequency of wounds of the external genitals in the present war resides in the multiplicity of the bits of metal derived from an exploding modern shell.

The proportion of wounds in remote regions from the genitalia (head, thorax, upper limbs) is in point of fact large because in the report referred to Cathelin found 16 instances of wounds in these regions out of a total of 32 cases of injury to the scrotum and testicle. And if we take into consideration the lesions of organs near to the external urogenital area, this same report informs us that the proportion is still greater. In these 32 cases of wounds of the genitalia the thigh was also injured in 27, the gluteal muscles in 2, while in 3 cases both thighs had been touched by the missile. From all this it may be concluded that all wounds from bullets or exploding shell, of the external genitalia, including the perineum, are more often than not accompanied by wounds of one or both thighs, usually on their internal aspect.

As to the frequency of scrototesticular lesions as compared to traumatism of the external genito-urinary areas, it may be said that here again statistics show the very great gravity of these wounds. In only 50 per cent. of the cases has the testicle been found intact. In the remaining 50 per cent. 9 times the testicle had been lost, either destroyed by the missile or removed surgically on account of its injury; in 5 cases the gland was atrophied, in 2 there was hernia of the testicle, and in 2 an abscess of the organ. Finally there was one case of traumatic orchitis, three cases of hydrocele, and two with a fibrous nodule in the epididymis.

As to the nature of the wounding agent itself there is nothing definite regarding the relative importance to be attributed to the various kinds of missiles. According to statistics of 24 cases given by Latarjet, 4 resulted from bullets, 15 from bursting shell, and 5 from exploding bombs.

Referring to Cathelin's report of December, 1915, he points out the great frequency of lesions from exploding shell. Of a total of 12 cases there were only 3 wounds from bullets as against 6 from exploding shell, 1 from shrapnel, 1 from grenade, and 1 from a torpedo. But it is to be remarked that these were all wounds observed under special conditions, while Latarjet's statistics refer to an offensive intermediary between trench and open warfare. Now, it is evident that the proportion may be singularly different according to circumstances. Without doubt the number of bullet wounds should be much larger in open warfare, for in trench fighting the greater part of the body is sheltered from bullets.

No matter what may be the nature of the missile, rifle or pistol bullet wounds are usually of the contused type. Certain smooth, sharp bits of shell act in just the same way as a bullet, but generally speaking a bullet will make a seton or linear wound, while bits of shell will cause extensive destruction or combine in their effect laceration, contusion and attrition of the structures involved. The damage alone varies. Sometimes it can be readily repaired, at others it will be serious, according to whether the scrotum alone is involved or whether the injury has compromised the vitality of the testicle.

Reeducation and Employment of the Blind.—Sir Arthur Pearson, himself blind and the head of St. Dunstan's College for the Blind, points out some essentials regarding reeducation of the blind. In answer to the question how his institution could teach in seven or eight months what it took others four or five years to teach, he said that if one tells a man he is afflicted, he becomes afflicted mentally and physically, but tell him he is handicapped and show him how to get over it, he becomes interested, his spirits rise, and he tastes the joy of achievement. Another potent factor is the blind teacher. It is intensely encouraging for the blind man to realize he is being taught by one who is blind. A third point is short hours. At Pearson's institution they work only two hours and a half in the morning and two hours in the afternoon. The newly blinded become brain weary if they stick too long at their work. It is difficult for people having their sight to understand this. The mental application needed is intense and unaccustomed. Progress is made only when the blind man has his mind tuned to a high pitch. Thus in seven or eight months the brighter class of men learn some trade, such as poultry farming, carpentering, book re-

pairing, mat or basket making, and they also learn to typewrite. Masseurs take longer, an average of twelve months. Pearson points out that those who are completely blind make far better progress than those who possess a little sight. It is important to teach the blind man not only to work but also to play. For the blind, adequate exercise is a problem. The four recommended are walking, rowing, swimming, and tandem-bicycling.

Gunshot Wounds of the Chest.—C. H. Fragge, writing in the *Guy's Hospital Gazette* for June, 1918, points out that until the end of 1916 physicians held that a chest should not be aspirated until three days had elapsed after the infliction of the wound. He thinks, however, that there is no evidence that if chests are aspirated within twenty-four hours of the infliction of the wound, which is about as early as a medical man makes up his mind as to treatment, there is an increased chance of recurrent bleeding. A large number of such wounds become septic and a very fatal complication after chest wounds is bronchopneumonia. Physicians have written much about contralateral collapse, which means collapse of the base of the lungs, but those who have operated upon these cases seem to know very little regarding it. From this one's own deductions may be drawn. It is possible that the physicians who write concerning contralateral collapse are influenced more by post mortem appearances than by what Moynihan calls "the pathology of the living." With respect to the form of anesthesia best adapted to the treatment of chest wounds Fragge states that so far as he could tell in comparing one casualty clearing station, where he was doing all the chest cases under local anesthesia with another where he was doing some of the urgent chest cases under general anesthesia, better results were obtained by the former method. A mixture of novocain and sulphate of magnesium with adrenalin was used. In Fragge's opinion, when general anesthesia is necessary, there is no anesthetic which can be given which compares with open ether, in spite of the disadvantage of occasional post anesthetic bronchitis. If the patient was given morphine ¼ grain one-half hour previous to operation, and if necessary another ¼ grain when he came on the table and then the novocain mixture was freely injected, and if before resecting the ribs the intercostal nerves were blocked by injecting the intercostal spaces with a long needle, getting as far back as possible, it was usually a complete success. The parietal pleura, which gets its nerve supply from the same intercostal nerves, can be anesthetized at the same time. There is evidence that the parietal pleura is sensitive, but there is no evidence that the lung is. Local analgesia allows of free manipulation of the chest wall and lining. If the hole in the chest is sufficiently large after resection of one or more damaged ribs, it is easy to introduce the hand, and if the foreign body has been localized by the *x*-rays it can often be removed, because if a foreign body goes into the lung it usually goes through it; therefore, as a rule, the foreign body will lie near the surface. This does not, of course, apply when there is a foreign body in the mediastinum. Local anesthesia is no bar to a complete operation, which is concluded as all operations on the chest should be by closure of the chest wounds. Fragge thinks there is no exception to this rule, unless the contents of the chest are found to be gangrenous. He never met with those cases in which there was sepsis of a gross kind in the lung; they were all early mild infections and there was no bar to closure of the pleural cavity. If the lung and pleura are infected with gas organisms they must be drained; if the chest wall is infected the deep parts of the pleural cavity should be, if possible, closed; the superficial part being left open. All these procedures are perfectly possible with a minimum of experience under a local anesthetic and without distressing the patient.

The Need for Discipline in Hospital Life.—While the same type of discipline found in an active, hardworking battalion cannot be demanded in the hospital, yet it is of vital importance that as high a state of discipline as is possible be maintained in order that habits of slackness, indolence, carelessness, and lessening of self respect may not develop. If the soldier is permitted to slacken physically and mentally, arduous work and effort are required when he rejoins his unit. Should he be discharged from the army in such a state of mental and physical slackness, he is then unsteady in principle, lacking in character, careless in habit, and therefore undisciplined, and as a result unfitted for the discipline of social and industrial life. He must soon become a part of the flotsam and jetsam of society and a non-producer. He joins the army of the idle and the indolent and drifts to the lower strata of society and is a burden to himself and a danger to the community. It therefore behooves society, the friends, the sisters, brothers, and sweethearts to do their share in helping to keep up a high state of discipline among the returned wounded heroes. This they can do by refraining from criticising or questioning the rules and regulations governing the conduct of the convalescent soldier which compel him to be in his bed at 9.30 P. M., to care for his personal appearance in every way, and to comply with all regulations laid down by those in charge of convalescent hospitals, which regulations cannot always be freely explained.

Government Entomologists Study Body Louse.—The Department of Agriculture, under the direction of the Council of Research of the Council of National Defense, is endeavoring to find preventives and exterminators for the "cooties" that not only annoy and irritate the soldiers but that spread trench fever and possibly other diseases among them. In the prosecution of these investigations a man who formerly served the city of Chicago in a public capacity is acting as host for body lice. Valuable data with regard to the control of the "cootie" have been obtained from the parasites living on his body and moving pictures of them have been taken through the microscope. The moving pictures are to be part of a campaign against these pests and show how the louse comes into existence, how it passes through the several stages of development and propagates its species. They will also show lesions caused by the bites

and how to find the eggs and the insects themselves in the folds of clothing. These will be added to films to be taken under the direction of the War Department which will show a delousing station, the devices used, and a company of men ridding themselves of their unwelcome visitors. One of the scientists of the Bureau of Entomology of the Department of Agriculture is also serving as a host for the parasites, but in a more restricted sense than the Chicago man. His "cooties" are confined under the glass top of a wristlet, much like a wrist watch, and pass their existence there. Through the glass cover the entomologist watches the "cooties" pass through all the stages of their life cycle. Efforts to devise ways and means of overcoming the parasites are being made by practically every country that has armies in the field. Thus far the body louse has not appeared in numbers in the camps of this country, but if it should do so the military authorities hope to be prepared to deal with it.

Less Illness in Training Camps.—For the week ended September 6 a general improvement in health conditions at the training camps in this country is noted. Ninety-five deaths were reported, compared with 117 the week before.

Influenza in the Army and Navy.—The epidemic of influenza in the first naval district, at Boston, which began several weeks ago has continued to spread. Up to September 16 more than 1,700 cases had occurred since the disease first made its appearance and 47 deaths had resulted. The Federal quarantine station in the harbor has been taken over by naval officers and 200 patients will be cared for there. A more recent report states that 8,000 cases of influenza have developed among the soldiers of Camp Devens, near Ayer, Mass. A request has been made to the Surgeon General's office to detail ten additional medical officers and forty nurses to the camp. Thus far there has been but one death from pneumonia resulting from influenza in the camp. The appearance of an acute respiratory affection similar to influenza is also reported from Camp Lee, which has led to an order prohibiting any gatherings in the camp. There are over a hundred cases of influenza among the naval forces stationed at New London, Conn. The naval men in this district have been forbidden to go out of New London for the present. At Camp Upton, among the 45,000 officers and men, 170 cases had been reported up to September 16 and the Camp has been quarantined.

Battle Creek Sanitarium Offers War Course.—The Normal School of Physical Education, which is affiliated with the Battle Creek Sanitarium, has inaugurated a course in Physiotherapy which meets the requirements of the War Department. The medical profession are asked to direct the attention of young women who are planning to engage in war work to this unusual opportunity. Four-month courses will begin October 1 and February 1. The curriculum consists of Anatomy, Physiology, Bandaging, Active and Passive Movements, Hydrotherapy, Massage, Electrotherapy, and Clinics. Further information may be obtained from Dr. Frank J. Born, director of the school.

Campaign for Nurses' Home in San Francisco.—The American Women's League, a nurses' aid of the San Francisco Chapter of the Red Cross, student nurses from local hospitals, and soldiers and sailors are conducting a campaign to raise $60,000 to equip a suitable home for San Francisco nurses who return from the battlefields of Europe exhausted from war work and who have no homes of their own.

Red Cross Head Goes to Europe.—Henry P. Davison, chairman of the American Red Cross, has gone to Europe to confer with those in charge of the field of American Red Cross activities in allied countries, so that no step may be overlooked in endeavoring to meet the increasing requirements of the American Expeditionary Forces. Mr. Davison will report and act upon all problems of relief that confront the American Red Cross overseas.

Major General William C. Gorgas, Surgeon General, U. S. A., accompanied Secretary Baker on his recent trip to France, arriving safely in that country on September 8.

Deaths in the Service.—Lieut. JOHN EDWARD WILLIAMS, a recent graduate of the College of Physicians and Surgeons, New York, and a member of the Roosevelt Hospital Unit, died recently in France from paratyphoid fever.

Dr. HAROLD G. PORTER of Syracuse, N. Y., attached to the naval hospital at Chelsea, Mass., died following an attack of influenza on September 11.

Review Women's Motor Corps.—The Women's Motor Corps of the New York Chapter of the Red Cross which is in charge of forty ambulances, recently went through a stretcher drill and unit formation in Central Park which was reviewed by army surgeons. Army officers commended the work of these volunteers.

Aid for Captured Nurses.—The American Red Cross announces that American nurses captured by the enemy will be supported during captivity by the Red Cross. This step has been taken to meet the situation created by the announcement of the War Department that under the law, army nurses, if captured, could not be paid, since technically they were not on military duty.

Army Still Needs More Nurses.—Acting Surgeon General Richards issued a statement on September 14 for the purpose of setting aright a misconception as to the need of the army for nurses. General Richards states that only 16,000 of the necessary 25,000 nurses are enrolled and available for active service. Before July 1, 1919, no less than 50,000 nurses will be needed; thus in less than a year more than 34,000 additional nurses will be required.

Medical Women Made Officers in French Army.—Dr. Caroline S. Finley, Dr. Anna I. Von Sholly, and Dr. Mary Lee Edward of New York, who are connected with the Women's Overseas Hospitals, have been decorated by the French Government and commissioned lieutenants in the Medical Corps of the French Army, the commissions having been bestowed for excellent surgical work and treatment of the wounded under heavy bombardment in a hospital at the French front.

INFLUENZA.

THE epidemic of influenza, which was here in mild degree in the early spring, has made the round of Europe and has returned to us in apparently somewhat aggravated form. There can be little doubt that it is genuine pandemic influenza, the same disease that prevailed so extensively in 1889 and subsequent years. Numerous reports have been given out that investigators had failed to find Pfeiffer's bacillus, but others again have found it. In Switzerland, which was sorely afflicted during the past summer, Professor Staehelin of Basle asserts that a study of the cases seen at the City Hospital there (*Correspondenz-Blatt für Schweizer Aerzte*, August 10, 1908) showed beyond doubt that the disease was true influenza, due to Pfeiffer's bacillus. The latter was found in the sputum and cultivated from the blood, just as it was 26 years ago. The clinical course was precisely the same, but instead of being milder than the ancient epidemic it was decidedly more malignant. The mortality was relatively high, for 50 per cent. of the populace were attacked and the total mortality during the epidemic was one per cent., due largely to pneumonia of influenzal origin.

There was a high morbidity from pneumonia among young adults which was less in evidence in the former visitation. Naturally in the great majority of cases the symptoms were those of uncomplicated influenza, chiefly fever, and the number of hospital admissions was very small, the patients being seen only when pneumonia had developed. The nervous and gastroenteric forms have been inconspicuous. Between June 16 and July 28 no less than 309 cases of pneumonia were admitted to the City Hospital, and of this number 46 died—about 15 per cent. As a rule the pneumonic complication set in slowly, heralded by a further rise of temperature, or, in other cases, by a peculiar cyanosis. The rusty sputum was absent and replaced by purulent matter, and autopsies showed that the condition was not typical lobar pneumonia, but lobular or pseudolobar in character. The pleura was usually involved to some extent. The dangerous feature in these cases was the bilateral location, although in many patients the spread of the disease in the lungs was very limited. The fatal element was bound up directly with the amount of lung tissue involved. Very significant in this epidemic was the presence of an undoubted leucopenia which has a prognostic value.

But little comfort is held out by the author on the score of treatment, for he says the passage of a quarter of a century has brought no new remedy to light, and salvarsan, quinine synthetics, and collargol were without influence on the disease. The most effective treatment, recalling the experience of the 1889-92 epidemic, consists in confinement to the house—to the bed if fever is present or the heart shows signs of weakness, a restricted but nourishing diet, and the administration of large doses of some salicylic preparation, preferably salicin. In the nineteenth century epidemic much harm was done with the indiscriminate use of antipyrine in overlarge doses, though an occasional dose of that, of phenacetin, or of salipyrine, may be called for.

GASTRIC PNEUMATOSIS.

THIS condition is a familiar one in civil practice, but occurring in the robust soldier in relatively good condition it presents numerous points of novelty. Professor Ceconi, who is consulting physician to the Second Territorial Army, contributes a monographic article in *Il Policlinico* for May 1 on palpitation, dyspnea, etc., which prove to be dependent on gastric distention. The malady is not, strictly speaking, a military one, but manifests itself in a certain type of soldier as a result of prebellum conditions. The age is around the 35 to 40 period, the subjects are inclined to stoutness; their occupations before the war were mostly sedentary.

The chief complaint is of dyspnea without any suggestion of cyanosis; respiration is rapid and superficial. The leading symptom referable to the heart is palpitation, usually associated with tachycardia. These symptoms may appear in crises and persist for from two to four hours; and at such times there are complaints of headache, vertigo, faintness, nausea, flushed face, cold extremities, etc. Associated with dyspnea and palpitation is a slight retrosternal oppression, and in certain cases the picture approximates that of angina pectoris.

These attacks tend to follow eating. The men are hearty eaters, and the meals are followed by an increase in abdominal tension. The interval after meals is one to two hours, and the picture develops rapidly. If the subject limits his meals the accesses are less pronounced. Belching and vomiting give relief, but the men are not inclined to spontaneous eructation, and induced belching is difficult. Some do not belch at all. There is usually a history of symptoms extending back to the age period 28 to 30. Most of the patients are nervous, and a certain number of them are true neurasthenics.

There is an appearance of illness in the facial expression, with pallor, prostration, moist skin, and

cold extremities. Respiration is usually between 30 and 40, with occasional deep inspirations. The breathing is eminently costal and Litten's shadow is absent. The condition is not a mere tachypnea but a true dyspnea. The area of cardiac dullness may be increased with the apex beat outside the nipple line. The pulse may reach 110, 130, or higher. The systolic pressure varies from 120-150. The *x*-ray shows that at the acme of digestion the diaphragm is in the high position, especially on the left side, where it is pushed up by the distended stomach. The latter is also responsible, in part at least, for the apparent enlargement of the heart, which is really displaced. If radioscopy is practised with the stomach empty, the diaphragm is seen in its normal position and in normal excursion, while the heart and aorta are also in the accustomed position. In a few cases in which the stomach contents were examined the gastric chemistry was approximately normal. In one the tube evacuated much gas.

It is by no means easy in these cases to exclude the presence of cardiac disease. True cardiacs often first consult the medical men for indigestion, and themselves suffer much from flatulence. Well marked cardiac neuroses of a permanent type appear to be gastrogenic at times. A short period of study and radiographic control ought to clear up all doubts. In the affection under consideration the disturbances occur only during digestion, and may subside even during this period if the gastric tension can be relieved. The nature of the pneumatosis is unknown, and the causation may be diverse. There may be a component of air-swallowing, or one of fermentation, or the mechanism may be vagotonic. Attempts have been made to show that negative intrathoracic pressure can exert a suction within the stomach. It has also been claimed that an abnormal mobility of the heart is the weakest link in the chain. One must always think of the possibility of hysteria, and, among soldiers, of simulation. But whatever be the nature, pneumatosis is the actual condition present. The diaphragm is also somewhat hypotonic. Finally a distinct predisposition is present, the patients having a short, capacious thorax and a tendency to corpulence.

"BACILLARY IMPREGNATION."

Often in the French medical literature the words bacillary, bacillosis, etc., refer in the absence of mention of other germs to the tubercle bacillus, especially in inoculation and septic states in which the role of the bacillus is well defined. Such a cycle is readily followed up in animal experiment—a primary lesion, general infection, and metastases. Ordinary apex tuberculosis would not belong here, for its mechanism is not clearly understood. In bacillary infection in the narrower sense the disease may first appear in the bronchial or mediastinal glands without a primary lesion. In other cases the latter may be in evidence. An old focus of tubercle may readily give rise to a bacillary case.

In an article by Ribadeau-Dumas and Brissaud (*Journal de médecine et de chirurgie pratiques*) the authors seek to show that certain cases of narrow chest, drop heart, etc., may be the result and not a cause of tuberculosis. An old tuberculous lesion, supposedly latent and harmless, dating from childhood, may actually interfere with normal development and cause a "cardiothoracic atrophy." In 375 cases tested 254 subjects were actually tuberculous, while the remainder seemed healthy, but clinical and radiographic tests showed evidences of ancient foci in the lungs (calcified spots). Small heart and drop heart were represented in a large percentage of cases.

The term "bacillary impregnation" thus becomes clear, for the germ has so impregnated the organism that a peculiar inferiority of development is the result. This means that the individual is first infected in early childhood—say between 2 and 8 years of age—and less frequently at a much earlier period, even as a nursling. Marfan has shown that these early cases may present no febrile reaction. Tuberculous infection early in life may appear under disguises which are not unmasked until a meningitis or acute miliary tuberculosis ends the subject's life. There is micropolyadenopathy; there are so-called tuberculides; there are peculiar forms of osteitis of the flat bones of the skull. In any obscure affection of childhood an *x*-ray picture of the lungs may reveal the underlying motive of disease. Individual case histories are often extremely illuminating. In one of these a child aged two years had a severe congestion of the lungs which lasted 6 months. At the age of 15 he presented cervical lymphademitis. Death was due to acute miliary tuberculosis, and at autopsy there was found a small calcified nodule in the base of the right lung (visible in the radiograph) with a caseous bronchopneumonia of the right apex and diffuse miliary tubercles. In bacillary impregnation we find clinically severe dyspeptic troubles, nervousness, effort dyspnea, cardiac fatigue, and tachycardia.

WOMEN WORKERS AND NATIONAL HEALTH.

It is obvious that the health of a nation very largely depends upon the health of its women. This is to say, that if women are not in sound health they cannot bear many or healthy children. It is equally obvious that never in the history of the world has there been a time when numerous and healthy children were so essential. In view therefore of the fact that women in Europe are engaged in toilsome labor of every description and also in view of the fact that similar conditions are likely to occur in this country, it is timely to consider the probable effect that such work may have upon the health of the workers.

While, perhaps, few will go so far as Sir Almroth Wright, who stated that women were physiologically unfit for work of an arduous character, at the same time it cannot be denied that the statement contains a considerable amount of truth. The physical make-up of women renders them less able

to undergo severe exertion than men, and if they do undergo such exertion for a prolonged period, their physical and nervous powers are drained to so great an extent that they are unable to produce many or virile children. In industrial countries this point has been demonstrated. The children of women factory workers are puny, undersized specimens of humanity, and this result is greatly due to the strain of long hours of labor, accentuated doubtless by the lack of mother's care that these children suffer. There are two outstanding reasons then why the children of women who work away from home are handicapped. First, because the woman worker is, as a rule, not in the physical condition necessary for the bearing of healthy offspring, and second, because she is not able to rear the infant as it should be reared, by feeding it at the breast. The war has turned everything upside down, and the labor of women is indispensable. It is only because women are able to take men's places as workers that victory is possible. But while the main object is to win the war, every effort should be made to conserve the health of the women workers. If this be not done, the future of the race is jeopardized. In the first place the pay should be fully adequate and in the second place the hours should be short, as it has been proved that really better work can be done by women in six than in ten hours and their health is not menaced. Good pay, which should be synonymous with plenty of good nourishing food, short hours, which should signify lack of fatigue, and working under first class sanitary conditions ought to be the normal state of affairs for women employed during these abnormal times.

The Preoperative Purge.

Some medical fashions change very slowly and one of these that has persisted for a time whereof the memory of man runneth not to the contrary is the custom of emptying the bowel by a brisk purgation preparatory to a surgical operation. The administration of a purge before an operation is, or was until very recently, a matter of routine in most, if not all, hospitals, and the interne or the nurse who had failed in that duty would be liable to a more or less gentle admonition from his attending surgeon if the delinquency happened to come to light. Of recent years, however, a warning here and there has been uttered regarding the possible evils of that practice. Five years ago Dr. Douglas H. Stewart of this city, writing in the *American Practitioner*, called attention to the evident ill effects of this procedure. Taking post-anesthetic vomiting as an index, he showed, in a series of 26 cases, that vomiting occurred twice when a purge had been given 72 hours before operation; it occurred three times when the purge was given 48 hours before; four times when given 24 hours before; and when the patient was purged 12 hours before operation vomiting occurred on the average four times the first day and twice the second; when a simple enema was given there might be slight vomiting, often but regurgitation of saliva, once or twice after the withdrawal of the anesthetic. A somewhat similar observation is reported by Dr. L. E. Emge, writing in the *Journal of the Americal Medical Association* of September 14, who remarks on the occurrence of gas pains in two series of 50 cases each, one series with pre-operative purgation, the other with none. Among the purged cases there were 37 patients who suffered from more or less severe gas pains; in those without purgation 17 only had "cramps" or pronounced gas gains. Emge comes to the same conclusion as Stewart, that an enema will clear the bowel sufficiently and that purgation is unnecessary and in a way harmful.

Italian Priority Claimed for "Bipp."

An Italian practitioner, Dr. Eduardo Calendra, writes to *Il Policlinico* of August 11 that he devised the familiar bismuth-idoform-paraffin paste as far back as 1908 and published a full account of it four years later in the sanitary periodical, *L'Ospedale di Palermo*, January-February, 1912. He understands that Mr. R. Morison did not publish his account of this preparation until 1917 and wonders whether his own description could have influenced the British surgeon in any way to devise a similar formula. His mixture was as follows: bismuth subnitrate 10 parts, paraffin 10 parts, idoform 4 parts, and olive oil 15 parts, which differs notably from the Morison formula. The latter contains no oil and a far greater proportion of iodoform. The Italian author devised his formula to fill up pathological cavities in bone and he seems never to have used it for any other purpose. He mentions Beck, the deviser of the bismuth paste for sinuses, but does not admit that this preparation influenced him in any way in the evolution of his own formula. "Bipp" was introduced into war surgery as a vulnerary, and in any case the genesis of a formula with only two active ingredients—for the paraffin and the oil are clearly meant only for excipients—might well come about independently in the practice of any surgeon.

News of the Week.

Surgeon-General Blue Issues Bulletin on Influenza.—According to statements given to the Associated Press, Surgeon-General Blue has made a telegraphic survey to determine the extent of influenza in the United States. He has found that there was a sharp outbreak at Fort Morgan, near Mobile, Ala., in August, and at about the same time a tramp ship arrived at Newport News with almost the entire crew prostrated. Philadelphia reported a few cases some weeks ago and a few have been reported from New York. An outbreak was reported in Boston on September 11. Since then the epidemic has appeared in New London, and a few cases have been reported from New Orleans. Because the last pandemic of influenza occurred more than twenty-five years ago, physicians who have begun to practise medicine since 1892 have not had personal experience in handling such a situation as is now spreading through a considerable part of the foreign world and has already appeared in this country, and for this reason Surgeon-General Blue has issued a special bulletin for physicians describing the disease and

the method of handling it. He also advises the public in regard to the early symptoms of the disease and the importance of seeking medical attention.

The Fourth National Exposition of Chemical Industries is to be held in Grand Central Palace during the week beginning September 23. More than 350 exhibits will be displayed and practically every phase of chemistry will be presented. The Federal Government was to have taken over the Grand Central Palace within a few days for use as a general hospital during the period of the war, but owing to the importance of this exposition has agreed to defer taking possession until October 1.

Jefferson Medical College.—The introductory address to the ninety-fourth annual session of the Jefferson Medical College, Philadelphia, will be delivered on Monday evening, September 23, by Dr. Jay Frank Schamberg. The title of the address will be: "Medicine—Then and Now."

Dr. Arnold Sturmdorf has been appointed Consulting Gynecologist to the Manhattan State Hospital, New York City.

Medical Society Dissolves.—The American Association of Medical Jurisprudence has been dissolved by order of the Supreme Court in compliance with an application for dissolution made by a majority of its directors. The association has no creditors and no obligations.

Red Cross to Collect Fruit Pits.—Since charcoal made from cocoanut shells, date seeds, the pits of peaches, apricots, cherries, prunes, plums, and olives, and the shells of all varieties of nuts is essential in the manufacture of gas masks, the American Red Cross has begun a nation-wide campaign to collect these materials which are usually wasted. Every Red Cross chapter in the United States will take charge of local collections and send the shells to the various collection centers. Special effort is being made to enlist school children and boy scouts in the campaign.

Deaths of Prominent Foreign Medical Men.—The editor of *El Siglo Medico*, calling attention to the loss to the medical profession in the deaths of Forlanini in Italy and Pozzi and Grasset in France, gives obituaries of three recently deceased Spanish medical men of eminence. The first mentioned is Eduardo Gereda, who was noted as a sanitarian and medical economist and publicist. His writings appeared in a publication in which he was a collaborator—*Semana Medica*. His name had been proposed for one of the most esteemed honors of his country, La Gran Cruz de Beneficencia, and he enjoyed the friendship of the King. A second prominent man to receive mention is Hipolito Fairen, dean of the Medical Faculty of Zaragoza, and a third, Juan Iranzo, professor of Clinical Medicine in the same institution. The former is regarded as the creator of the modern University of Zaragoza and a monument to his memory will be erected in the gardens of the hospital. Dr. Iranzo, in addition to his medical eminence, was elected Alcalde in 1909 and took part in numerous civic and other reforms. He was a member of distinguished foreign medical societies.

The death of Dr. Oscar Wyss of Switzerland was reported recently. He was born in 1840, was graduated in medicine in Breslau in 1862, and was at once offered the post of assistant to Lebert, the pathologist. When the war with Austria broke out in 1866, he went to the front and was placed in charge of a hospital for sick and wounded Austrians. After time spent at Prague and Vienna after the war he returned to Zurich and became a member of the medical faculty of the university. In 1874 he was placed in charge of the new Children's Hospital. In 1883 he was made professor of hygiene and director of the new Hygienic Institute. Eventually he became both Dean and Rector of the university. He was identified at various times with pathology, clinical medicine, pediatrics, hygiene, and toxicology, and was a recognized authority in all of these spheres of activity. He inspired over 200 graduation theses during his teaching career. In his thirty-six years as director of the Children's Hospital he made a majority of the autopsies with his own hands.

Dr. Sape Talma, the well-known clinician of Holland, died last June as a result of prostatic disease. Like the majority of medical men who gain fame in small countries his activities were numerous, both within and outside the profession. He was born in 1847 and matriculated at Utrecht in 1866. In 1876 he was made professor of pathological anatomy in the University. He was no less interested in physiology and experimental medicine. At a later period he received the chair of internal medicine. He was quite an exception to the rule that men who become prominent in after life must study abroad and neither before nor after his graduation are any journeys to foreign schools of learning mentioned. His biographer emphasizes the fact that he was an autodidact. The well-known operation of Talma for the relief of cirrhosis of the liver has given rise to the impression that he was an operating surgeon. Talma was highly valued as a teacher and his forty years of activity coincide accurately with the development of modern clinical medicine in his native land.

Obituary Notes.—Dr. Daniel Worrell Jefferis died at Chester, Pa., on September 1 at the age of 80 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1865. He was a member of the Delaware County Medical Society (at one time its president), of the Medical Society of the State of Pennsylvania, and of the American Medical Association. He was a physician to the Chester Hospital and president of the Medical Advisory Board of the Selective Draft. He had been coroner of Chester, for many years president of the Board of Education, for several terms president of the Select Council, and also Mayor of Chester.

Dr. William Francis Waugh of Chicago died on September 5, at the age of 69 years. He was graduated from the Jefferson Medical College in 1871 and was for a time in the Medical Corps of the U. S. Navy. After leaving the Navy he practised for several years in Philadelphia, and in 1890 removed to Chicago. He was professor of medicine in the Illinois College from 1894 to 1904, and in 1909 was appointed dean and professor of tropical medicine in the Bennett Medical College.

Correspondence.

OUR LONDON LETTER.

(From Our Own Correspondent.)

THE MENACE OF MEASLES—PUBLIC HEALTH AND POLITICAL PROGRESS.

London, August 21, 1918.

Nothing is more interesting in the natural history of epidemiology than the manner in which the different infections change their measure of virulence from time to time, so that an ailment whose mortality has hitherto been negligible becomes a scourge of the community, while a pest that once was held in general awe loses its terrors for the public. The case mortality of infectious disease in London as revealed by the just published annual report of the Metropolitan Asylums Board illustrates this position very well. The Metropolitan Asylums Board is the controlling authority of the fever hospitals of the metropolis, and to these hospitals are sent such cases of notifiable infectious disease as for various reasons cannot receive treatment within their own homes. As might be expected, the statistics of such institutions deal particularly with scarlet fever and diphtheria, and in these respects the death-rates for 1917 are found not to have altered materially from a decennial average. The case mortality of diphtheria, which fell rapidly some 20 years ago after the introduction of antitoxic treatment, remains for 1917 practically what it was for 1916, viz., 6.7. The case mortality of scarlet fever, which is only 1.9, is also greatly lower than it was at the end of the nineteenth century, and here no obvious reason exists for the change. It can be fairly attributed however, to two things—improvement in public sanitation, so that the environment of the patient at the time of attack is not prejudicial, and improvement in the standard of medical equipment, so that earlier diagnoses are made and the patient comes more quickly under intelligent treatment. The report of the Metropolitan Asylums Board for 1917, as far as scarlet fever and diphtheria are concerned, is very cheerful reading; nor do we want to postulate some change in type of the actual infecting germ to understand the amelioration in public health which has taken place. But when we turn to measles the report tells a totally different story. Nearly 3,000 cases of measles were admitted during 1917 to the hospitals of the Board, and of these 11.7 per cent died, the death-rate being higher than any figure since 1911, and by that time measles had begun to take the place in medical opinion which scarlet fever had previously occupied—the place, namely, of being the most dangerous infectious disease to which childhood is subject. No reason on the surface exists for the increased virulence of measles such as exists for the lessened virulence of diphtheria, and there is evidently room here for a valuable research. One other disease has lately become more serious in type in this country, and the figures of the Metropolitan Asylums Board indicate as far as they go the increased measure of risk. Of 391 cases of whooping-cough in the medical hospitals of the Board 13.4 per cent. died, the death-rate being the highest on record. It must be remembered here, and to some extent the remark holds good for measles also, that the death-rate in he hospitals of the Board does not reveal the average case mortality outside, because it is only the cases with serious complications, such as bronchopneumonia which are admitted. None the less the figures prove what medical men have recently come to regard as a fact, that measles and whooping-cough are the two most dangerous threats to child life in urban conditions.

The position of Ireland is for obvious reasons an extremely embarrassing one, not only for Great Britain but for all the nations fighting for the Allied cause against the Central European Empires, and especially for the United States of America, where Irish national aspirations have received such generous support. Fortunately—for the task would be indeed a difficult one—there is no onus in a medical paper to discuss the underlying political questions which have led to the existing situation. No attempt need be made to evaluate how far bad government by Great Britain, religious prejudices and antiquarian sentiment in Ireland, manufacturing greed, agrarian ignorance, and treacherous interference by Germany with Irish politics, have played a part in the confusion which exists; but one factor in that confusion has a distinctly medical significance, and plays a great part in every issue—that factor being the abominable condition of public health in Ireland and the inadequate nature of the public medical service of the island. The rural districts of Ireland are cared for medically by the officers of the Irish Poor-law Medical Service. These doctors, too often placed in their posts for other than medical reasons, are overworked, ill-paid, and unsupplied with material assistance in such matters as hospial and laboratory accommodation, or expert and consultant opinion. They are unable to afford to the districts in which they practise any standardized sort of medical care comparable to what might be expected in an integral part of the British Empire in the twentieth century. Ireland is a sparsely populated island, at any rate to-day, and in spite of its enormous potential wealth, notably in the direction of agricultural and fishing industries, the population is a poor one, the significance of this being that the officers of the Irish Poor-law Medical Service cannot expect any addition to their official salaries from the fees of private patients. Here, however, it may be said that Ireland is not much worse off than many parts of Scotland and some of the more sequestered districts of England; general public health organization and administration may be more behindhand, but this obviously matters the less when the population is small. To reduce this point to absurdity there is no central drainage or water scheme in the Sahara Desert, and the number of persons who would benefit by the innovation is not large enough to warrant the expenditure. But in England and Scotland the persons below a certain income level come within the scope of the Medical Benefits Clauses of the National Insurance Act, which clauses do not run in Ireland. Also the public health in Ireland is not seen to be so bad in those sparsely populated rural districts. Ireland is at fault in public health administration in its great cities, and this has a most serious ef-

fect on the birth-rate, sick-rate and death-rate of the country, and may well be playing a serious part in promoting political unrest. While, for example, the death-rate of London, with a population of over four millions, was, in the first week in August, only 11 per cent., that in Belfast was 15 and in Dublin nearly 16. In both these great cities the expectation of life at all ages is 40 per cent. below what it should be, while the infantile mortality is correspondingly heavy. From every point of view it stands to reason that if these two cities, which comprise within themselves two-thirds of the urban population and in which are concentrated two representative classes of political thought, enjoyed a higher standard of public health, political questions would be approached in a far more wholesome manner. And this is why the inauguration of a comprehensive housing scheme for Dublin is an important event. Dublin is a great medical center, and the medical men in Dublin have enjoyed for many generations high prestige as exponents of their profession in every division and speciality. Yet the public health of their city has been their despair, for it is impossible to keep down the ravages of such diseases, for example, as tuberculosis and infantile diarrhea when the population live in a perpetual environment favorable to the incubation and spread of pathological conditions. Dublin medical men therefore, and for the reasons set out above all thinking people must share the feeling, are delighted to read that the Engineering Inspector of the Irish Local Government Board, Mr. P. C. Cowan, has submitted to the chief secretary in Ireland a plan for dealing with the rehousing question in Dublin, which will be really drastic and made possible by a lavish use of money. The scheme entails an expenditure of from eight to nine millions of state money. Mr. Cowan sets out the necessities of the case as follows:

"Sixteen thousand new self-contained houses to prevent overcrowding and to permit the separation of the sexes; the improvement by remodeling of 3,803 first and second class tenement houses, in which 18,991 families now live, so that the total number of remodeled houses may afford suitable accomodation in tenements of from one to four rooms for 13,000 families. Sixteen thousand is estimated as the number of new houses required. These houses, if built in continuous rows on each side of a street, would be 25 miles long, and it is suggested that they should be erected by a board representing the Government, the city of Dublin, the urban districts, and the Dublin County Council."

Mr. Cowan estimates the expenditure which will have to be faced under two headings of rebuilding and reconstruction, and for the 16,000 new houses at £400, asks for £6,400,000. The acquisition and reconstruction of 3800 old tenements, he believes, would cost £2,040,000. Those who do not know what a beautiful city Dublin is may be surprised at the possibility of acquiring such a large number of old houses which could possibly be adapted by reconstruction to the purposes of a central sanitary scheme. Dublin, as a matter of fact, is full of magnificent houses quite capable of intelligent alteration. Neglect, unrest, and lack of money have made Dublin shabby, while the city bears the scars of the recent *émeute;* but nothing can take away from it the character of a historic capital. But for the month of July last the death-rate of Dublin was 30 per mille! And the total of death exceeds the total of births, showing that the efforts of sanitation are ineffective. The rehousing scheme is fraught with happy possibilities, medical and political.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

BOOKS FOR THE SOLDIERS—FINDING AMERICAN WOUNDED IN FRENCH HOSPITALS—THE SPANISH INFLUENZA—ROSA BONHEUR'S CHÂTEAU—ANNA MORGAN COMMITTEE LOSE MILLIONS—RED CROSS OBLIGED TO FLEE FROM GERMANS—HOSPITALS AT NICE.

PARIS, August 6, 1918.

THE work of the American Library Association in France is developing rapidly. Within the past three weeks about half the districts in which the A. E. F. is located have been covered with at least a sprinkling of books, and within a few weeks every district will have received its first quota. During April, 55,000 books were shipped, so that the total will be well above the 100,000 mark. As to the future supply, the nation-wide campaign conducted by the American Library Association has netted more than 3,000,000 volumes, and it will be continued to the end of the war. These donations are largely of up-to-date fiction. Supplementing this, the A. L. A., from its war fund, has purchased nearly half a million special technical and reference books, which are being shipped to special units. Over each collection will be posted this placard:

These books are for your use without charge.
They belong in this building and are to be returned to it within the time prescribed.
To borrow a book, fill up the card found inside the back cover and hand it to the librarian.
When you return the volume, see that the record against you is cancelled.
These books are loaned on the honor system. If you fail, it fails.
America is far away, tonnage scarce, and books precious. Play square with the other fellow; he has played square with you.

And in facsimile will be this pithy statement, signed by the commander-in-chief himself: "These books come to us overseas from home. To read them is a privilege: to return them promptly, unabused, a duty.—John J. Pershing."

In the last week, the workers of the American Fund for French Wounded located 103 Americans in various hospitals and delivered their names and reports of their condition to the Home Communication Service of the Red Cross, which then took the cases in hand. The A. F. F. W. workers often find boys awaiting evacuation in French Hospitals where scarcely a word of English is spoken. The joy of the boy who finds some one "from home" sitting by his bedside ready to hear his story and see that some special want is filled can be imagined. The following extract from a letter from one of the workers is interesting to Americans: "Yesterday we made our first call at the ——— Hospital, and visited all the American men. One poor lad had been trepanned, one lieutenant had lost a leg, many were suffering from gas, but all with the most

wonderful spirit, and all wanting to get back into the lines. They gave us such a welcome, saying we were the first American women they had seen; were we here to remain, and would we come again? We found some of our own marines, and I do wish you could have seen their faces when they recognized us."

Madrid is very much alarmed by the strange sickness which is now epidemic. Though it is mild in character, none of the cases having proved fatal so far, it causes much anxiety because the doctors declare it to be an unknown malady, and it spreads rapidly. There is hardly a house without one person sick. In the theaters, programs have to be altered daily on account of artists suddenly falling ill. The newspaper staffs have been very much depleted. In Government offices the same state of affairs exists. At the chief post office forty employees were taken yesterday to the hospital, the total number of the sick being already 115. At the barracks there are large numbers of sick soldiers. One regiment has 300 men in bed. A military band could not attend a ceremony because half of the musicians were ill. Physicians are bewildered. They cannot attend to all the calls upon their services, and confess they do not know what the trouble is.

According to *La Accion*, the symptoms—vomiting, fever, diarrhea, and acute pains throughout the body—correspond to those of influenza. This newspaper states that the epidemic is due to the turning up of the earth during excavation work for the underground railway, sewage schemes, etc. The same thing occurred at Caracas, in Venezuela, when such underground works commenced. The United States Government sent a commission to study the epidemic, and the report concluded that the digging operations unloosed microbes such as played havoc in the times of the Spanish conquest.

The château of Rosa Bonheur, the animal painter, near Fontainebleau, has been converted into a hospital for French wounded, as previously reported. The room Rosa Bonheur used to like the most is kept in the same state as when she died, with flowers in a vase and her gloves in the same place, all showing the devotion of her friend, Miss Anna Klumpke, the American artist, who is the owner of the property. Miss Anna Klumpke and her mother are doing heroic work for the French, giving up their entire time to the wounded who are sent to the hospital. Miss Klumpke said in reply to questions: "The wounded we are caring for are paralyzed by enemy shells. We have a group of fifteen men at a time, and our staff is made up of twenty-four people in all. It is our mission to instill confidence into the hearts of these poor fellows in order that the mutilated ones may learn a trade and become useful units in society. You must have heard of the fine work of the Union des Colonies Etrangères for the mutilated of the war. Workshops have been opened, in this connection, at the Grand Palais. Our small formation has become an annex of this union. Every day, except Thursdays, from one to four o'clock in the afternoon, the men sit or stand around a large table, and, under the direction of a monitor, who, by the way, is also wounded, these poor fellows work at making cardboard boxes or at bookbinding. When they become sufficiently skillful they receive payment for their work. We encourage them to sing and whistle during their hours of work so as to forget as much as possible the horrors through which they have gone."

Millions of dollars' worth of property which was being used by Miss Anne Morgan's committee for the reconstruction of towns destroyed by the Germans in the early months of the war was captured by the Prussians. When the extent of the devastation wrought by the Germans in their first dash into France was learned, Miss Anne Morgan organized a committee and raised a fund of millions of dollars to help the French peasants rebuild their ruined homes. The work was heralded as splendid in character, and was regarded by the French people as most commendable. Forty-three villages were to be rebuilt. Some of them were almost complete ruins. Millions of dollars' worth of building material was imported from America and a vast supply was purchased in France. For two years Miss Morgan and her associates had been engaged upon the task, and many of the ruined places had been completely restored, to the joy of the peasants, who in many instances had been rendered not only homeless, but penniless as well. When the renewed German offensive started it was realized that some of the property might be endangered, and it was hurried south. The great bulk of it, however, remained, and has been destroyed by the enemy.

It is as evident in the center of France, far back of the lines, as it is in the very thick of the fight, that the young American Army has swung into line with full force. All is activity at the supply depots. Those that have been in construction for the last six months are now well organized and working as if they had been a part of the war since 1914. The canteens are feeding thousands of soldiers on their way to and from the front, and the big hospitals are filling rapidly. At this particular center is one of the large base hospitals that came to France last July. The personnel is the Harper unit from Detroit, and the entire organization is almost an exact reproduction of the Detroit Hospital. It comprises 1,200 beds, and now has 1,000 patients who have been recently wounded at the front. All of the wounded are in excellent spirits, and their one thought is to get well enough to go back to the front.

The Red Cross Canteen, which is entirely in charge of American women, has been doing excellent work. During the last few days the military trains have been passing one after the other in rapid succession, and the canteen workers have been kept busy day and night. Huge baskets of good American bread, chocolate, and cigarettes, are always ready to be distributed for each train, and there is always a supply of lemonade and cookies and plenty of hot coffee at all hours. Everything runs so smoothly that 600 men are served in fifteen minutes with no difficulty whatever, and each soldier is made happy by having his pockets filled with good things to eat by an American woman. Adjoining the canteen is an infirmary and rest station with twenty baths and shower baths.

The work among the refugees is an important feature at this moment. There is scarcely a village from Paris to a distance of 200 miles south that is not filled with refugees, and every vehicle from a

wheelbarrow to a hay wagon has been put in use. While the famous war relief organizations are looking after thousands of refugees there are still hundreds along the roadside, wandering about with their packs on their backs, searching for a place where they can find rest.

In the drive last spring and early summer the Red Cross personnel at the front have often been in places of danger, but so far only one member has been slightly wounded, and all are now in comparative safety. There has been no serious loss of supplies, even the wheelbarrows stored in Soissons having been used by the refugees to carry away effects. Canteens at the front, Nos. 2, 4, 5, and 7, between Soissons and Rheims, were captured by the Germans in their drive toward Paris, but all the men were able to make good their escape ahead of the rapidly advancing enemy. Convoyers to start three new Franco-American canteens at the front were sent out early this week. This brings the total number of these canteens up to fifteen. The sixteenth will soon be established.

Many of the wounded American soldiers who are being tended at the American Hospital at Nice, in company with French wounded, are from the States of Washington, New York, and Massachusetts. Maj. Kent Monnet is the doctor at the hospital. The Americans have been fifteen months in France, and for the most part are unacquainted with the language. Nearly all of them belong to storming units employed in the front line, and have come from Champagne, where they have rendered yeoman service. There is one sergeant among them, all the others being privates, who are suffering from rheumatism or wounded. Their condition is not serious, and they are not forced to remain in bed. They follow the same régime and are fed and treated in every way like the French patients. There are twelve Americans, a British officer, a Canadian non-commissioned officer, a Senegalese, and thirty-five Poilus now under treatment at the hospital. The morale of the Americans is excellent. Although they are delighted with their surroundings, they are anxious to get back to the front. They arrived at Nice in company with French and British wounded. The latter are being cared for at the Victoria Hospital, the Grand Hotel, and at Les Palmiers.

A hospital where none but British wounded will be received is being organized at Nice. The Americans will probably remain about three or four weeks there. The *Eclireur de Nice* reports an incident which demonstrates the Franco-American brotherhood of arms. Some American officers, ill or convalescent, encountered by chance two or three French officers and soldiers in one of the big hotels here. Among the latter was a Poilu with his arm in a sling and wearing among other decorations the Croix de Guerre with palms, and decorated with the Legion of Honor. One of the Americans, who has but a slight knowledge of the French tongue, took an English interpreter aside and said: "I am a lieutenant. I shall be promoted captain as soon as I return to the front. Tell this French soldier that I lay down my own rank to salute him respectfully." It is easy to understand the emotion that was felt by all present.

3. **Is It Worth While for the Man of Fifty to Get Into Physical Condition? Conservation of Man Power at or Beyond Full Maturity.**—J. Madison Taylor discusses the question at some length, and decides that it is worth while. Nature demands personal co-operation, and this is particularly true when full maturity has been reached. Naturally judicious moderation must be exercised. From his experience—both personal and professional—Madison Taylor believes that systematic training always benefits unless there exists some latent defect, which should have been discovered and guarded against, and he points out that the problem of structures giving way to physical strains is one thing, and to the toxic biochemistry of the body-formed poisons (anaphylaxis) is another. Certain fundamental facts should be borne in mind by everyone: The motor impulses of childhood are divinely implanted instincts for the acquisition of symmetrical development, contributing to safety and efficiency as an animal and also to intellectualization. Unless habitual body use is encouraged, along with suitable opportunities for the play of spontaneity, full competency is never attained by the individual. It is possible, however, even in late life, to repair weak spots, and the author cites an instance of a man who from a state of feebleness at forty-five, through progressive outdoor activities became a man of splendid mental and physical capacity even at sixty-five. Another case cited is that of a business man of fifty-two years of age who suffered from digestive disturbances, irregularities of sleep, and of heart action, fatigue, susceptibility to cold, etc., and who at sixty-five is a model of vigor, endurance, and resistance to cold and disease, capable of accomplishing four times as much as before. His structures are all elastic, his muscles responsive, controllable and normal as those of a man of thirty. This was effected by gradually inuring the skin to exposure, and to frictions by brush and hands; exercising nearly nude, but securing elasticity by simple free movements followed by full relaxations; by systematic breathings and long walks; together with a modified diet along lacto-vegetarian lines. Contrary to the general opinion, little time and effort are required to get into condition. Vital processes are stimulated by renewals of any form of mental or physical activity. It is important to insist upon hygienic measures and educative exercises that will establish a due proportion between food intake and outgo of waste products, and between inherent powers of motion and such use of active parts as shall maintain mobility, elasticity, pliancy, hence motor competency not only for direct use but for supplementing the oxidation processes. This can be done by keeping in mind plain rules of posture and completeness of movements commonly employed. In addition to this, all that may be demanded is a few moments' daily of fundamental movements in normal directions; or if not daily, twice or thrice a week. By attention to diet and personal hygiene it is often possible not only to reacquire good health, but to develop unsuspected latent powers. The important question is not what one should eat, but rather how one eats and how much one eats. Underfeeding in certain states is a peril, but in a much larger group overfeeding is a direct, perhaps the sole cause for organic derangement and degeneration. An excess of protein food results in a large group of hurtful effects. Horace Fletcher has demonstrated the value of proper mastication of food, and for temporary purposes a reduction of diet to simplest articles and the smallest variety is of life-saving efficacy. When digestive processes or harmonies are in doubt, simply

omit one or more meals till equipoise returns. Much is to be said in favor of a diet of nuts, fruits, cereals, with or without milk and eggs. An excess of meat and sugars should be avoided; alcohol is objectionable. Few factors in personal hygiene are more important than the care of the skin. Friction, with the faithful use of the flesh brush, is superior to the careless bath. To avoid the evil effects of chill, of catarrhal states, and to keep the kidneys in good order, few measures are superior to salt friction baths. As a routine procedure Madison Taylor recommends the following: On rising throw off the clothing and rub the entire body briskly for five minutes; resume a covering and proceed with the toilet; or better, take a sponge bath, using a rag dipped in cool water on which is placed a small handful of salt. Rub this thoroughly all over the body, rinse off with cold water, and rub dry.

4. A New and Highly Efficient Dressing for Wounds.—Alfred Kahn suggests the use of blotting paper as an internal dressing or drain, or an external absorptive dressing. He also suggests the use of punctured paper adhesive on one side as an external binder, to take the place of the cloth roll or bandage. This adhesive paper roll can be variously medicated and used in the same way as adhesive or mustard plaster; it is less expensive and can be more easily removed and destroyed. Kahn has employed such a dressing for surgical cases for some years, particularly in the packing of the mastoid cavity. In conjunction with syringing he often packs the paper, the material used being medicated with various antiseptics. He has obtained excellent results with blotting paper, either plain or medicated, used as a wet dressing over contused wounds and highly inflamed, irritated surfaces. In furunculosis of the external auditory canal, he has used it soaked in a solution of aluminum acetate. In furunculosis associated with diabetes, and for carbuncles, abscesses and furuncles of the neck, this dressing has proved excellent. In the treatment of deep lacerated wounds, as a cigarette drain wrapped in some stiff material such as rubber tissue, it has proved superior to a gauze drain.

1. The Lumleian Lectures on Celiac Disease. Lecture II.—G. F. Still described in the first Lumleian lecture the clinical features of coeliac disease, assuming the condition to be a specific entity. In the second lecture he turns to a discussion of its pathology. Morbid anatomy has afforded no specific clue to the cause of this affection. Marked thickening of the wall of the bowel, however, has been noted, a feature which is not present in cases of gastroenteritis or ileocolitis, when the wall often appears thinner than normal. Inflammation involving the whole of the intestinal tract, obvious to the naked eye as well as to microscopic examination, was also noted in two cases. Whether these appearances are primary or secondary is not known. It is possible that they may be due to some specific bacterial agent; bacteriological examination, however, has failed to throw light upon the question. In six out of eleven of Still's cases, evidence of infection with a dysentery bacillus was found, and in some cases serum was found to agglutinate this organism. It is probable that in some of the cases, if not in all, there is a primary infective catarrh of the bowel, which is due, in some at least, to the dysentery bacillus. On the other hand, the *fons et origo* may be some profound digestive disturbance and not infective at all. One of the most characteristic clinical phenomena of the coeliac disease is the pale stool, with appearance and smell suggestive of excess of fat. Dr. Cammidge has estimated the fat in three of Professor Still's cases as 26.9, 73.1, and 42.5 per cent. Herter found there was a loss of 20.25 per cent. and even as much as 40 per cent. of the ingested fat in one of his cases, whereas the normal loss in health varies from 2 to 8 per cent. Failure to absorb fat may be due to various causes which fall into two categories: (1) lack of preparation of the fat for absorption through deficiency of the fat-splitting function of the bile or of the pancreatic secretion; (2) failure of the intestinal surface to absorb, in spite of the fat being sufficiently prepared by the fat-splitting processes and saponification. It would seem that in some cases at least, the biliary secretion is deficient; this was so in two of the author's cases, but in a third case there was no apparent diminution of stercobilin. As for pancreatic insufficiency, no direct evidence of this has been furnished either by clinical investigation or laboratory examination of the stools. It would appear, therefore, that, although in individual cases the biliary secretion may be found deficient, there is no interference with the fat splitting process which prepares fat for absorption. The fault, then, must lie in failure of the absorptive function of the intestinal mucosa. It is possible that this may be due to functional failure, but it is more probable that the first step in the disease may be a catarrhal condition of the mucosa

in the small intestine, where in health the absorption of fat occurs chiefly or entirely. If this is so, however, it is difficult to see why the failure of fat absorption should be so much more pronounced in coeliac than in other diarrheal conditions. Professor Still next considers congenital syphilis as a possible cause of the condition. The Wassermann test was performed in six cases, in three of which it was positive. There was no clinical evidence of syphilis in any of these cases and treatment with mercury was of no benefit; moreover, the parents and relatives who were tested gave a negative reaction. Commenting on this, Still states that these findings would seem to support the view that there are other conditions besides syphilis which may give a positive Wassermann. One of the most noticeable symptoms in coeliac disease is dropsy occurring in the distal parts of the limbs and in the face, and sometimes associated with ascites. Professor Still suggests that this symptom may be determined, in part at least, by toxic absorption from the intestines. Two factors would seem to corroborate this—puffiness of the eyelids, especially of the lower eyelids, accompanying chronic constipation or chronic indigestion; and general edema with albumin in the urine and no evidence of organic disease. He has observed that in some wasted infants the edema corresponded closely with variations in the degree of unwholesomeness of the stools and seemed to be more influenced by that than by the number of stools. This applies to cases of coeliac disease and he suggests, therefore, that the edema be regarded as due in part to feeble circulation and hydremia and in part to toxic absorption. Purpura is another symptom which sometimes recurs for years in coeliac disease. It is to be noted that the stools decrease in frequency before the purpura appears, and it is possible that the delay in the evacuation of unhealthy feces may cause absorption which results in the purpura. Mere constipation does not produce purpura and it has been suggested that indol may be the poison in question. This is rendered probable by the fact that during the presence of purpura a marked indican reaction was noted in the urine in many cases. The occurrence of tetany also points to toxic absorption. The arrest of growth, which is such a distinctive feature of coeliac disease, may be caused by deficiency of fat absorption. Experimental evidence would seem to give color to this suggestion, but it is not apparent how deficiency of fat in diet has any special influence in arresting growth. Herter has shown that there is an appreciable loss of calcium with the soaped fat passed in the stools, but calcium deficiency does not necessarily inhibit growth as is shown in the case of cretins given thyroid treatment at an age when walking has recently been acquired. There is also evidence that fat deficiency in the diet is a large factor in the causation of rickets, and there is deficient calcium deposit in the rachitic bone. It would be expected, then, that rickets would be closely associated with coeliac disease, whereas the reverse is the case. Furthermore, if the failure of fat absorption be the cause of the stunting in celiac disease, arrest of growth might be expected far more commonly in rickets.

Berliner klinische Wochenschrift.

July 8, 1918.

The Nature of the Weil-Felix Reaction in Typhus Fever.—H. Braun has been led by his experiments to explain this reaction as follows. It is due to an increase of certain normal agglutinins, this resulting from the action of the typhus fever and these agglutinins are, in quite a fortuitous manner, particularly active against certain strains of the Proteus. In order to explain this multiplication of the normal agglutinins, the writer invokes the very special localization of the agents of typhus fever. Since Nicolle's researches, it is known that these agents are more particularly contained within the leucocytes. This localization causes a marked excitation of the leucocytes and is thus the cause of the exaggerated production of normal antibodies. This peculiarity, which belongs to typhus fever, explains still more the fact that the Weil-Felix reaction is quite special to this disease.

On a Disease of Influenzal Type.—K. Kroner publishes a study which entirely relates to the epidemic which has ravaged Europe during the past few months. He describes the affection, now familiar to the profession, as being absolutely influenzal in nature, but differing distinctly from true influenza by the three following circumstances: (1) The almost general absence of Pfeiffer's bacillus, (2) distinct leucopenia, and (3) bradycardia in a large number of cases.

An Experimental Analysis of Subfebrile Temperatures.—J. Holló and E. Holló-Weil describe a subfebrile type of temperature which is absolutely refractory to antipyretics, but on the other hand, is influenced by opium. Such cases are frequently wrongly considered as latent tuberculoses, but in reality are merely instances of a particularly labile sympathetic nervous system.

Münchener medizinische Wochenschrift.

July 2, 1918.

Orthostatic Albuminuria. — Beckmann and Schlayer have endeavored to verify the theory which supposes orthostatic albuminuria to be the outcome of a disturbance of visceral innervation, and more particularly to hypertonia of the autonomous nervous system (vagotonia). Injections of atropin, adrenalin, pilocarpin, etc., have demonstrated that frequently the orthostatism is met with in a vagotonic soil, but this rule is far from being constant. An injection of atropine caused the final disappearance of the albuminuria in one case, while in several others the albumin disappeared for a time. Therefore, atropine would seem to be the specific remedy of orthostatism should this condition require treatment.

The Early Diagnosis of Whooping-Cough.—Chievitz and A. K. Meyer publish a continuation of their bacteriological researches on whooping-cough. Their technique consists in causing the patients to cough on a culture medium composed of agar-agar, potato, and blood, which is quite like the one associated by Bordet and Gengou. The writers' classification of their results arranged according to the stage of the disease is particularly interesting and is as follows: Catarrhal stage, 77 per cent. positive results; convulsive stage, 1st week, 52; 2nd week, 50; 3rd week, 30, and 4th week, 10 per cent. positive results. In the fifth week no results were obtained. In no case of non-pertussis infection could a culture of the Bordet-Gengou bacillus be obtained. Therefore, these researches would seem to show that the contagiousness of whooping-cough is limited to one month, in spite of the fact that the affection continues longer.

Deutsche medizinische Wochenschrift.

July 4, 1918.

Exanthemata in Paratyphoid A.—Nobel and Zilezer have had the opportunity of observing an epidemic of paratyphoid A which was peculiar from the frequency of a roseolic eruption of a very intense type. Clinically the epidemic assumed the characters of a moderate typhoid. The bacteriological diagnosis agreed in 6 cases in which the culture on bile were positive. The writers particularly insist on the histologic findings from specimens of skin removed by biopsy. The process was of an acute inflammatory type, consisting in a congestion of the cutaneous capillaries and edema, and a perivascular infiltration including both the large and small lymphocytes, as well as various cell types. Small hemorrhagic foci were met with in certain areas. These lesions were absolutely different from those met with in typhus fever in which the primordial histological picture consists in changes of the vessel walls with ultimate thrombosis. Microscopical examination of the cutaneous manifestations thus allowed the writers to eliminate typhus fever in certain instances of doubtful paratyphoid. On the other hand, the cutaneous lesions of this affection are not sufficiently distinctive from those encountered in other forms of erythemata.

Chemotherapie Disinfection with Quinic Alkaloides and Their Derivatives.—J. Morgenroth and E. Buncke offer their results derived from a series of researches *in vitro* tending to dissociate the quinic molecule into

derivatives quite as active as quinin and forming new combinations possessing even greater power. The writers do not give the detail of the manipulations, but they compare the intense bactericidal action of the products obtained to that of products already known, this action being far greater in antiseptic power than even bichloride of mercury. As to Dakin's solution, the writers only assert its small value as a bactericidal agent without having made any comparative experimental studies with this solution and the quinic products.

Wiener medizinische Wochenschrift.

July 6, 1918.

Diagnosis and Treatment of Contusions of the Abdomen.—H. Finsterer offers a paper on the above subject in which the remark is made by the writer that the malarial spleen appears to be particularly susceptible to rupture and that the presence of a slow and strong pulse, after the phase of shock has passed off, does not exclude the possibility of a ruptured liver, should be mentioned. The latter phenomenon is attributed by the writer to the absorption of the biliary acids. Abdominal rigidity, the presence of an intraabdominal fluid collection, localized or radiating pain, are all symptoms too well known to require lengthy discussion. The writer ends this article by proposing to make a small abdominal exploratory incision in all doubtful cases, rather than blindly remove a blood or fecal collection by puncture.

Clinical Observations on Pleurisy.—F. von Becher, from his studies on the thermic evolution and the etiology of pleural collections, believes that the polynuclear elements are more prone to accompany the high temperature cases while the lymphocytic formulæ belongs to those cases in which there is little or no temperature. Generally speaking, the thermic curve in high temperature cases assumes quite a uniform type with a progressive ascension during two to three weeks, the maximum lasting from one to five days followed by a drop in lysis. Convalescence is interrupted by small thermic elevations but which never attain the elevation of the fever existing during the stage of full devèlopment of the process. Puncture of the thorax with removal of the fluid is frequently followed by a rapid drop in temperature. Relapses are usually preceded by a marked rise in temperature before the pleural exudate can be detected.

Le Progrès Médical.

May 26, 1918.

Psychonervous Pain.—Bernheim refers to pains without appreciable lesions—although such pains may once have had an organic substratum—of which he gives numerous examples. A boy of 9 complained of severe sensitiveness in the umbilical region which he believed evidently to be due to a slight excoriation. He cried out if the area was touched. By suggestion of the insinuating character Bernheim managed to touch the area without invoking the pain complex and the sensations vanished for good. A young woman vomited a lumbricoid worm and thereafter experienced pain below the appendix region with sensations of crawling in the throat. Bernheim could produce pressure pain almost anywhere in the abdomen. He banished the pain in the groin by suggestion but to combat the crawling feeling and nausea it was necessary to give worm medicine. An elderly day laborer complained of pains in the armpit after a heavy lift and had to quit work. When he resumed a week later the pain was still there. Bernheim found a number of places in which pressure pain could be induced. Forms of effort pain were not associated with a material basis. He was cured in three days by suggestion. A domestic believed she had strained her back and for five months complained of pains in that region which were lancinating and with tendency to exacerbation. She was free from pressure pain areas and her gait was not affected although the sensations were radiated along the limbs. She had lost much sleep. Under suggestion sleep became good and she slowly improved. Bernheim cites numerous other cases of the same type and states the medical man does not know all that takes place in the organism. More remarkable than the case of this type is another in a man of 61 of a high class who had never been ill in his life but had suffered for thirty years from pains in the sole of one foot. There were numerous sensitive pressure points. No fixed tender point could be found in the foot although both feet showed vague tenderness. Walking was not interfered with and the man was given to dancing and hunting trips on foot—could walk 16 kilometers without getting footsore in any way. Bernheim, laying his hand on the patient's head, told him the pain was only in the brain. Distracting his attention, he pressed on one of the numerous dolorous areas and no pain reaction followed. But initial improvement was not maintained; 30 years' duration had given too deep roots to autosuggestion.

Norsk Magazin for Laegevidenskaben.

May, 1918.

Myasthenia Gravis.—Monrad-Krohn relates two cases of this affection. Special emphasis is laid on the necessity for timing the swallows in eating, so that the weakened muscles have a short interval for recuperation. This should measure from 2 to 4 minutes. The food must not be so hard to chew that mastication is an effort. A myasthenic must never be allowed to drink from a cup or glass but must receive fluids from a spoon; the rapid sequence of deglutition reflexes in drinking quickly fatigues the muscles concerned and choking and bronchopneumonia may result. Drinking is also believed to favor the development of attacks of dyspnea, although these can also occur spontaneously, and the nurse—every myasthenic must have a nurse—must be familiar with manual methods of artificial respiration. The passive exercise of the muscles involved does not prevent the recuperation of the pharyngeal muscles. It may be advisable to use the Sylvester or some other method for half an hour, an hour, even two hours. There is no causal treatment. The patient can only be nourished, rested and protected from death by dyspnea. Very often he recovers, sometimes, indeed, merely as a result of resting. Tube feeding is expressly contraindicated because of the danger of setting up exhausting pharyngeal reflexes and of the possibility, in the absence of all reflexes, of the entrance of the tube into the trachea. Rectal feeding is sometimes useful. Strychnine is also contraindicated for it increases reflex excitability. Recommendation of the use of this drug in so many text books is unfortunate. This disease was first studied in the author's clinic in 1887, although Oppenheimer reported it first and Erb had isolated the bulbar syndrome in 1879.

Missed Labor with Living Child.—Arnesen reports a case of transverse presentation at term in which labor began only to cease again. An attempt was made under narcosis to dilate the os manually in the hope of extracting a foot but was given up in the presence of the cessation of all signs of labor. Six weeks later there was spontaneous delivery of a living child, well developed and only of middle size. It was not weighed. No cause for the transverse position was apparent.

Meningococci and Gonococci.—Aaser and Holst discuss the subject of the possible confusion of gonococcus and meningococcus meningitis. Observers in the eighteenth century described a gonorrheal rhinitis and in 1830 Eisenmann featured a gonorrheal meningitis. Progress along these lines remained at a standstill for many years despite the ever increasing knowledge of the pathogenicity of the gonococcus. Finally a series of endocranial manifestations developing suddenly in the course of the disease—for example, diplopia—were very suggestive of a meningeal localization. The extragenital manifestations of gonorrhea also show a certain parallelism with the extracerebral complications of epidemic meningitis. Each form of coccus can cause a sepsis and metastases without implication of the meninges. The remarkable resemblance between the two causative organisms suggests that in a purely bacteriological or serological diagnosis, mistakes are possible. There is the further possibility of other germs of like behavior which belong to neither species. In any supposed epidemic of meningitis this question of possible identity can be subjected to intensive study.

One should at least know if meningococcus serum can agglutinate the gonococcus and vice versa. Thus far the elaborate study of the authors has failed to prove that any of the diplococci obtained from the cerebrospinal fluid of patients with epidemic meningitis are gonococci. Again in gonorrheal patients, none of the diplococci obtained from the nasopharynx are gonococci. The fact that an antimeningitis serum can inhibit the gonococcus cannot be interpreted as demonstrating the identity of the two organisms.

Correspondenz-Blatt für Schweizer Aerzte.

May 11, 1918.

Determination of Diabetic Acidosis by Measurement of the Tension of the CO_2 of the Alveolar Air.—Rapin and Turin mention the shortcomings in the recognition of acidosis. Urinary acidity is not sufficient in all respects, and requires laboratory technique. Furthermore, the urinary tests presuppose the integrity of the kidneys, for in inadequacy the acids are retained. In any case, what is wanted is not the amount of acid in the urine but that in the organism and also the state of the body defences against acidity. There is one simple procedure—the determination of the amount of alkali necessary to render the urine alkaline. This does well in certain degrees of acidosis but is not dependable when the latter is very high. Normally the alkalinity of the blood corresponds to about 50 ccm. of normal sodium hydrate for each liter of blood. It is due to the presence in the plasma of a certain quantity of acid sodium carbonate and phosphate which can blue red litmus paper. Such alkalinity is only apparent for the salts on which it depends are really acid salts in which an atom of it is replaceable by one of a metal. Hence authors speak of blood acidity although the blood is best regarded as neutral. There are, it must be admitted, alkaline reserves in the blood which can combine with CO_2. If the latter accumulates in the blood these reserves can be shown to diminish. Minkowski showed that in diabetic coma the CO_2 in the blood is strongly diminished, probably because the oxybutyric acid has been able to saturate the alkaline reserves. CO_2 is combined in the blood in numerous fashions—as sodium carbonate and bicarbonate, sodium phosphocarbonate, carbohemoglobine and in loose combination with the blood globulines. The capacity for combination with the alkalies of the phasma is diminished in acidosis. The CO_2 tension in the alveolar air is equal to the difference of the oxygen tension in the inspired and expired air, = 37 to 38 mm. of mercury at ordinary air pressure. To obtain this tension Joslin, also von Noorden, use the apparatus of Fredericia. The authors have sought to devise a simple bedside apparatus for this purpose and have had constructed a device termed by them the spirocarbometer. A bulb holding 100 c.c. is provided with two valves. A narrow reservoir in the lower portion below the entrance opening contains potassium 60 per cent. An upward extension of the bulb is provided with a manometer. The lower valve being opened the patient breathes through it by means of a mouth piece, the upper valve which leads to the manometer being also open. At the end of expiration the valves are closed (the lower first) and the manometer removed. The apparatus is now inverted, so that the potassium enters the bulb, and then shaken for a few moments, after which it is righted. Care must be taken that the hand does not warm the bulb. The manometer is now replaced, its valve opened and the difference between the two measurements read off. It is radily apparent that as acidosis increases the CO_2 tension diminishes. Thus with acetone in the urine of a patient 1.37 the CO_2 tension was 36; with acetone 2 84 it was 34, while with acetone 4.18 it was but 21. A number of successive measurements are necessary, as individual readings at long intervals would be misleading. In operating the apparatus, however, several corrections must be made. The tension recorded by the manometer is much higher than 37 or 38 because it comprises the vapor tension and runs from 45 to 55 or more in the normal subject. Correction for temperature does not appear to be absolutely necessary. In a severe case of acidosis the uncorrected alveolar tension ranged from 42 to 21 mm. Hg., while in an ordinary diabetic the figures were within normal limits. In a case of beginning coma the range was from 47 to 22, the higher figures appearing as a result of treatment. When the urine approached and reached alkalinity the tension had risen steadily from 22 to 47; and when the urine once more turned acid there was a drop in tension from 47 to 41.

Hygiea.

April 30, 1918.

Two Operative Cases of Hemolytic Icterus.—Edman reports two congenital cases of this affection in a mother and child and one case of acquired hemolytic icterus due to syphilis. The two former were subjected to splenectomy with the result that one month after operation all of the symptoms, save anemia, had disappeared. Five months after the intervention the latter symptom had also vanished. The author believes that the icterus may have resulted from absorption by the intestine of urobilin in excess, due in its turn to an excessive production of bilirubin. The absorbed urobilin again becomes oxidized to bilirubin. Wessén adds an account of the pathological specimens—spleens removed from a mother and son aged respectively 57 and 18 years. The spleens weighed 1400 gms. and 1120 gms. To the naked eye no alterations were perceptible; to the microscope the alterations were of a common character. There were changes in the medium sized and smallest arteries which comprised hyaline degeneration and proliferation of the perivascular tissue. The malpighian corpuscles were coarser than normal; the trabeculæ also showed hyaline degeneration; the meshes were as if compressed and contained a relatively small number of lymphocytes—in fact, the picture of lymphoid tissue was lost. The pulp showed a peculiar richness of blood with a peculiar distribution. The venous sinuses were empty and the intervascular stroma full of blood. The proper pulp cells were reduced in number and were thrown well into the background by the number of erythrocytes.

Case of Hemolytic Icterus.—Antoni also reports a case of this affection. The patient was aged 20, female. The mother is said to have had jaundice for a long time but was later free from it. No other heredity of interest. The icterus followed a surgical operation. The girl is fat, shows general icterus, spleen slightly enlarged. Hemoglobin 70, red cells 4,325,000. Feces reddish brown. Urine normal. Wassermann negative. Bloodsugar 107 mgm., increased by adrenaline to 171. The patient was splenectomized and the icterus vanished for a time, to reappear. At present time there is a slight tint in the skin and conjunctivæ.

Origins of Medical History in Spain.—Dr. Garcia del Real of Valladolid writes of the medicine of the Moors, Spanish Jews and French Benedictines. Little is known of Spanish medicine before the days of the Moorish invasion. The older Iberian and Celtiberian languages are all but unknown and have left no monuments. We know about as little of the medicine of the Carthaginian and Greek colonists. A few fragments of Hispano-Roman medicine have come down to us, but these are insufficient for drawing conclusions. This takes us to the epoch of the Visigoths which should have been sufficient to destroy any beginnings of medical culture had such existed. It appears from a work known as the Forum Judicum that before this irruption there were activities in the realm of preventive medicine and forensic medicine. The accomplishments of the great Arabians and of Maimonides and his coreligionists are of course sufficiently well known to us. The Christian culture of the period seems to have been in the hands of the French Benedictines, who were famous for their learning. This could obtain only in the northern kingdoms which had never been permanently conquered by the Moors. In the thirteenth century the Christians established the first universities and the first hospitals in Christian Spain (with the exception of a lazaret erected by the Cid in Palencia in 1067 A.D.).—*Revista Ibero-Americana de Ciencias Medicas.*

Book Reviews.

A Medical Dictionary. By W. B. Drummond, M.B., C.M., F.R.C.P.E., Medical Superintendent, Baldovian Institution, Dundee. Price, $5.00. London and Toronto: J. M. Dent & Sons, Ltd.; New York: E. P. Dutton Co., 1918.

This excellent work is not intended for the medical practitioner, though he might read some of the articles with interest, but for the layman—for "social workers, school teachers, district visitors, clergymen, factory inspectors, and welfare superintendents"; for "those who are called upon for medical knowledge, preventive or curative, in the absence of professional help."

The author has done his work well, avoiding the common errors of using too technical language and of telling his readers too much in regard to treatment, thereby imparting to them the little learning which is so dangerous a thing, especially in medicine, tempting the half instructed to give powerful drugs for minor ills which simples or time alone would cure. Many of the articles are capital and, as we have said, of interest even to the professional reader, especially those on the borderline of medicine, such as the relation of insects to disease, trade diseases, including those of munition workers, and eugenics, and others dealing with hygiene and public health, such as ventilation, food, exercise, water supply, vaccination, bacteriology, etc.

The educational value of the work would have been increased had the author included more of the history of medicine; in the article on yellow fever, for example, not enough is said of the discovery of the mosquito's agency in spreading the disease, and the practical wiping out of the scourge in most of the endemic centers by the application of this newly acquired knowledge. While teaching the layman the principles of first aid and giving him more or less information regarding the nature of disease, it would have been well to let him know something of what the much abused profession has actually accomplished in advancing the science of sanitation and safeguarding the public health.

Applied Bacteriology. Studies and Reviews of Some Present Day Problems for the Laboratory Worker, Clinician, and Administrator. Edited by C. H. Browning, M.D., D.P.H., Director of the Bland-Sutton Institute of Pathology, Middlesex Hospital. New York: Oxford University Press, American Branch, 1918.

This little volume is the joint work of seven men, including the editor. The different chapters are in part written jointly by two or three contributors. They really represent a series of detached essays which deal incidentally with enteric bacilli, the diphtheria group, the coli group, tetanus, antiseptics, the isolation of certain bacteria, the selective action of thallium acetate and the ultra violet rays, the chemistry of antibodies and the use of calibrated pipettes in serological work. It is therefore almost wholly a book for technicians. In works of this type the essays are usually mere reprints but in this case there is no evidence that any of them have appeared elsewhere.

Principles of Surgical Nursing: A Guide to Modern Surgical Technic. By Frederick C. Warnshuis, M.D., F.A.C.S., Visiting Surgeon, Butterworth Hospital, Grand Rapids, Michigan; Chief Surgeon, Pere Marquette Railway; Secretary of the Michigan State Medical Society; Editor of the Journal, Michigan State Medical Society; Member of the Michigan State Board of Registration in Medicine. Octavo of 277 pages with 255 illustrations. Price, cloth, $2.50 net. Philadelphia & London: W. B. Saunders Company, 1918.

This book is written from the point of view of an active operating surgeon who can fully appreciate the value of the properly trained nurse in the operating room as well as the value of competent nursing before and after the operation. Conversely, he well knows by experience the blighting effect on the smooth technique of the operating room and of the actual operation itself when the operating room staff of nurses has not been properly trained. He should, therefore, be well qualified to deal with this subject from a practical standpoint; and it takes but a brief perusal of this book to confirm that opinion. He has written in a clear, concise and logical manner, giving an interesting as well as eminently practical exposition of the subject, while the abundance of excellent illustrations adds still more to its value.

The methods taught in this book are largely if not entirely those of the hospital with which the author is connected, but that would also be true of books by other authors, since each would recommend the methods to which he was accustomed and which appeared to him to be best. It is also likely that a nurse at the head of a Training School would wish some portions of the text elaborated for teaching purposes and would consider others verbose or perhaps even unnecessary; but while the book is not perfect, it certainly will furnish any nurse with a set of guiding principles which, if followed closely, will make her unusually expert and efficient in the handling of surgical cases.

A Manual of Histology. By Henry Erdmann Radasch, M.S., M.D., Assistant Professor of Histology and Embryology in the Jefferson Medical College, etc. With 307 illustrations. Price, $2.50. Philadelphia: P. Blakiston's Son & Co., 1918.

This work is a successor of an earlier one, but is virtually a new work necessitated by the great advances of recent years. The chief departures appear to be in technique and in neurohistology. About 90 of the 564 pages are devoted to nerve substance and the nervous system and 55 to general technique. The alimentary tract requires 73 pages and the connective tissues 38 pages. All of the remaining sections are considerably smaller. The illustrations are on a rather small scale because of the size of the volume and the absence of colored plates is probably the result of war contingencies. It is difficult to predicate the teaching value of such a book from a survey of its pages, but the work is admirably done by one who thoroughly knows his subject, and must be regarded as authoritative.

Local and Regional Anesthesia. With Chapters on Spinal, Epidural, Paravertebral, and Parasacral Analgesia, and on other Applications of Local and Regional Anesthesia to the Surgery of the Eye, Ear, and Nose and Throat, and to Dental Practice. By Carrol W. Allen, M.D., Assistant Professor of Clinical Surgery at the Tulane University of Louisiana, New Orleans; Lecturer and Instructor in Genito Urinary and Rectal Diseases at the New Orleans Polyclinic; Visiting Surgeon to the Charity Hospital. With an Introduction by Rudolph Matas, M.D., Professor of General and Clinical Surgery at the Tulane University of Louisiana, New Orleans, etc. Second Edition. Price, $6.50. Philadelphia and London: W. B. Saunders Company, 1918.

Dr. Rudolph Matas states, in an introduction to this book, that since 1895 he, as director of the surgical clinics of the College of Medicine of the Tulane University, supervised efforts made by the staff to diminish the indications for general narcosis, and to substitute for the immediate dangers of chloroform, which was then the routine anesthetic in almost all Southern clinics, the more laborious but far safer methods of peripheral analgesia. For a period of something like fourteen years experiments have been made at Tulane University in this direction, until at the present time, while the art of local and regional anesthesia is only in its adolescence, great advances have been made in this branch of anesthesia. The book before us is a review and summary of such progress, written by Dr. Carrol W. Allen, who has for many years devoted himself to a study and practice of local and regional anesthesia. So skilled indeed has he become in these methods that from 55 to 60 per cent. of the major operations at the Charity Hospital at New Orleans, in the division under his charge, are performed solely by peripheral anesthetic procedures, exclusive of the spinal or subarachnoid analgesis, which are not included in this category.

This second edition includes the advances made in this field, prominent among those being the removal of the prostrate, which Dr. Allen regards as his best accomplishment in local anesthesia.

The work deals with local anesthesia in all its details and is a valuable reference book on the subject. It is well illustrated.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Twelfth Annual Meeting Held at Albany, May 20-24, 1918.

(Special Report to the MEDICAL RECORD.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

Second Day—Wednesday, May 22.

DR. JAMES KNIGHT QUIGLEY IN THE CHAIR.

The Value to Both Mother and Child of Prenatal Care.—Dr. RALPH WALDO LOBENSTINE of New York presented this paper. He said the expectant mother had been neglected too long; too long had the "leave it to nature" delusion occupied our minds. Never before had the nations been brought to such a keen realization of the value of the mother. Recent investigations had shown that very little attention was given to parental care and that this was true of the rural districts more than of the cities. For instance, a study of one county in Kansas where the level of prosperity was high showed that two-thirds of the mothers had no medical care before the children were born. In many parts of the country the conditions were even worse. Practically 40 per cent. of all deaths under one year were due to congenital disease. To this must be added the high still birth and miscarriage rate of which there were no reliable records. In endeavoring to combat infant mortality and maternal morbidity, we were fighting industrialism, with all its attendant horrors, poverty, filth and ignorance. The basic evils that we had to combat were ignorance, rum and ruthless industrialism. If we could remove the curse of alcohol, the others, poverty, filth, syphilis and tuberculosis would in a large measure disappear. In New York the situation had been studied from different angles, the efforts having been confined to Manhattan with its 2,500,000 population and its 60,000 or 65,000 births every year. The first step in the simplification and coordination of the work was the development of the zoning system, as outlined in the *American Journal of Obstetrics*, September, 1917, whereby Manhattan was divided into ten zones. The basis adopted was the ratio of existing maternity facilities to the number of births in the different sections of the borough. The district plan was important for hospitals, for lay organizations, and most of all for the patients themselves. It encouraged the hospitals to draw their clientele from their particular district and rendered prenatal oversight of the expectant mother far easier by economizing the time of both the patient and the visiting nurse. The maternity center would be the center of an educational campaign for the prenatal care of expectant mothers of the district in which it was located. It would be the coordinating agency or the clearing house for the expectant mothers of that zone. It would secure the opening of prenatal clinics, conveniently located, when enough of such clinics did not exist to serve the needs of the district. The doctors and midwives of the district would be urged to bring their cases to the clinics for consultation. These clinics would be open day and night for emergency cases. Women physicians would be employed because of the prejudice of foreigners against a male physician. The clinic would follow each birth and see that nursing care was provided throughout the danger period. All the clinics would be standardized so far as records, nursing and medical oversight. Efforts would be made to encourage all abnormal cases to go to the hospital. Standards of requirements for prenatal care had been formulated for both hospitals and maternity center clinics, urging early registration of all expectant mothers and constant supervision. Literature giving instructions to expectant mothers was prepared and distributed.

Injuries at Birth, Their Effect upon the Child and Their Prevention.—Dr. BARTON COOKE HIRST of Philadelphia presented this paper. He stated that about 10 per cent. of children died prematurely of asphyxia, atelectasis, malformations, injuries, and infections. He then discussed in detail the injuries that might occur to the various parts of the body. Injury to the brain was most frequently the result of the faulty use of the forceps or the violent extraction of an aftercoming head. The nerves most frequently damaged were the facial and brachial plexuses. Spoon depressions of the parietal and frontal bones were most often caused by a prominent promontory by forceps. For the correction of these depressions pneumatic traction or trephining had been suggested and Dr. L. C. Frazer had successfully operated on one such case for him. Fractures, if compound, required aseptic dressing. Distortion of the head was very common. Caput succedaneum was a common injury to the scalp, requiring no treatment and usually disappearing in three or four days. Cephalohematoma occurred about once in 200 cases. It was due to subpericranial hemorrhage which lifted the pericranium from the bone, irritated it, and stimulated it to bone production, thus giving rise to the bony sensation at the lifted edges of the pericranium, and later to a peculiar crepitus over the tumor. Non-interference was the treatment except in cases in which the hemorrhage was excessive or suppuration had occurred; the latter required incision and drainage. Sloughs required ordinary surgical treatment, as did fractures and dislocations. Decapitation had been known to occur in some cases in which undue force was exerted and occasional injury was inflicted on the cervical spine, the larynx, or the trachea, in consequence of the excessive twisting of the neck that occurred when the occiput turned forward from a posterior position and the shoulders did not follow the movement of the head. Injuries to the limbs were usually fractures, being as a rule a separation of the diaphysis and epiphysis. They required in the lower extremities fixation in extension, and plaster bandage and in the arm fixation in the Velpeau position by a jacket with only one armhole for the sound arm. Fractures were usually the result of faulty management on the physician's part. Avulsion sometimes occurred in efforts to extract a premature or macerated fetus. In discussing injuries to the trunk, the essayist stated that ruptures of the large bowel might result from pre-existing ulceration or necrosis, usually at the sigmoid or other flexures. It was obvious that a great many of these grave injuries were due to faulty obstetrics. Specialists and the better trained element of the profession had definitely given up forcible deliveries of all kinds. Hard forceps operations with hours of strenuous pulling were no longer performed. When the head could not engage first the former plan of doing a version to try to pull it into the pelvis by main strength had been abandoned. Mistakes in diagnosis resulting in applying forceps to the breech or to one buttock or forcing a blade between the scalp and the skull were cited. The prevention of these injuries must result from better education in obstetrics than former generations of medical students had had.

Some Causes of Stillbirth.—Dr. J. CLIFTON EDGAR of New York presented this communication. He said the term stillbirth in this paper applied only to viable fetuses, namely, from twenty-eight weeks of pregnancy to term, in which respiration was not established, whether heart action persisted or not. The percentage of stillbirths in the United States and the number of deaths of infants in the first months following labor had shown no decrease during recent years. During the year 1917 there were 141,564 living births in the city of New York and 6,120 stillbirths were reported to the Department of Health, although the actual number of the latter must have been very much higher. There was a stillbirth mortality of 4.1 per cent. Of 14,468 births at the Manhattan Maternity from April, 1905, to October 1, 1916, there were 519 stillbirths or 3.6 per cent. The object of this paper was to inquire into the immediate causes of these 519 stillbirths with the possibility in view of lessening this source of infant mortality. The cause of the stillbirth was unknown in 149 cases; it was due to obstructed labor in 78; protracted labor in 32, and precipitate labor in 19 cases. It was due to cord conditions in 65 cases, to placental conditions in 47, maternal diseases in 44, and fetal conditions in 65 cases. In ten cases the cause was unstated. The writer made a detailed analysis of these groups of cases and in commenting on the findings deplored the absence of the routine employment of the

Wassermann reaction. At least one death in the series was attributed to the employment of so-called twilight sleep. Unless employed with great judgment, pituitary extract in labor cases was often a double-bladed instrument. To what extent chloroform, ether, and nitrous oxide gas were contributing or direct causes of stillbirths was an open question. Prolonged anesthesia during labor must always be reckoned with as predisposing to stillbirth. In this group of cases anesthetics were used very sparingly. The great lesson the study of these 500 instances of stillbirths taught was the need of prenatal observation and care of the patients. It was difficult enough to persuade the patients of the upper classes that such care was imperative; it was often impossible to convince the tenement house patient. In the hospital from which these cases were taken a daily prenatal clinic was conducted to which patients were directed to report and to send specimens of urine, etc. In connection with the Bellevue service they held a prenatal clinic twice a week. The conclusions they had drawn had reference to several possibilities, namely, a better system of records, a greater proportion of autopsies and biological tests, diffusion of knowledge among actual and prospective mothers, and especially oral instruction of women who have once been confined, so that better supervision might be exercised during the next pregnancy. In a word, better general obstetrical care, with special regard to closer prenatal observation of pregnant women. In regard to the number of cases in which the child might have been born alive under favorable auspices, many of the protracted labors could be included, precipitate labors might be added, and also some of the dystocia cases, especially those due to faulty presentations. Toxemia and eclampsia could have been averted in a goodly proportion of the cases. All of the syphilitic cases might have been averted by early treatment of the mother. It was by no means unlikely that at least 100 cases might have been saved, and even this seemingly high estimate might be too small a computation. Although their mortality was lower than the average there was every reason to believe that this figure could be considerably decreased. The tenement house woman was especially prone to abortion and premature labor which could not be charged to physical injury or psychical shock to the mother, but of which the real underlying cause was the too early getting about after confinement, before involution was more than partially accomplished, with the resulting subinvolution, displacements and endometrial changes. The longer existence of these conditions led to an even earlier interruption of pregnancy.

The Establishment and Maintenance of Breast Feeding.—Dr. J. D. Crozer Griffith of Philadelphia presented this communication in which he said that provision for the establishment and maintenance of breast feeding should be taken, if it were possible, before the mother was born. There was no question that the ability to nurse an infant successfully was to a large extent a matter of inheritance. It seemed very probable that a line of mothers who, though able, practised a voluntary refusal to suckle their offspring, finally developed an acquired characteristic which could be transmitted, resulting in inability in the mothers of the younger generation to perform the maternal function of nursing. Were we able to follow out the principles of eugenics to their logical conclusion a young woman before being permitted to marry would be subjected to an examination of her mammary glands to determine whether they were of a size and form which would make the ability to suckle probable, and in addition her mother's personal experience in maternal nursing should be investigated. It might be noted that inability to nurse was to a large extent a matter of locality. In certain regions of Germany nursing was common and in others infrequent. In Japan artificial feeding was almost unknown. Another important influence upon the establishment of breast feeding was the manner in which the mother had been brought up as a girl. It went without question that, in the average at least, the woman whose girlhood had been passed in the most hygienic manner would be the best purveyor of food for her infant. It was the neurotic mother who was liable to give the poorest milk, if any at all, and after her child was born it was often too late to make attempts to obviate the difficulty. In studying the problem of the inability to nurse, the conclusions were unavoidable that unwillingness played a very prominent rôle. This was to a very large extent the fault of the physician in attendance at the time of confinement. The growing desire of women of the better class to nurse their children came from what they had learned at the numerous mothers' clubs and publications in the lay press, and the like, and not to the degree that it should from the advice of the medical profession. In many other instances it was through the advice of a too officious obstetrical nurse that the effort to nurse the baby was given up by the mother. If medical men would unflinchingly preach the dogma of maternal nursing to their clientele, it would not be many years before we would see a marked increase taking place in the number of women able to nurse their children. A secretion that was not well established by the third day might yet be established if given a little longer time. When the secretion was slow in being established, frequent pumping of the breast might be of advantage. It sometimes happened that a weakly infant was unable to suckle satisfactorily and the breasts were left constantly too full; nothing would so soon diminish the supply as this insufficient emptying. Another very important factor in the maintenance of the maternal secretion was the preservation of a normal psychic state. In every instance in which a mother had an insufficient supply an attempt should be made to give the infant *supplemental* and not *substitute* feedings. Sometimes this might be avoided by allowing the infant to nurse from both breasts at one feeding. Later in the infant's life the question arose of the advisability of giving one or two bottles a day. There was no surer way of causing a cessation of the milk secretion. A better way was that of giving some supplemental feeding after each breast feeding. There was now a plan in vogue for the reduction of the number of feedings as compared with the practice of the past. The experience of many authorities showed that the average normal breast-fed infant emptied its stomach in one and one-half to two hours and was therefore ready for food again should the giving of it seem advisable. The longer the intervals the less stimulation of the breast occurred and the greater the danger of the milk supply diminishing. Large amounts of liquid given to the mother to augment the milk supply were likely merely to dilute the infant's food. Cow's milk given to the mother offered no advantage over weak tea or even water provided the mother was already well nourished. The mother gorged with milk cocoa and the like was liable to have her digestion disturbed. Malt liquors undoubtedly increased the supply of milk in some instances. The advisability of administering them varied with the case. Exercise had a distinct influence upon the composition of milk. Over-fed women who took too little exercise were liable to have a milk too rich in solids, especially the protein and fat. Menstruation had little if any influence on the character of the milk. Galactagogues were usually this in name only. From what had been said it was evident that breast milk could be modified to only a very limited extent. The effort should be made to regulate the life on a normal hygienic plane as far as possible and to eliminate all causes of worry.

The Care of the Premature Child in the Home.—Dr. Herman Schwarz of New York read this paper in which he gave a short résumé of the essentials necessary in the care of the premature infant, giving particular attention to temperature, nourishment, and nursing care. He said the temperature of the premature infant was usually lower than that of the normal infant, and was characterized by greater fluctuations, usually in the downward direction, and on the temperature a prognosis could usually be made. In order to combat this lowered temperature the application of heat was necessary. If the baby at birth had a temperature of less than 94° F. the prognosis was very bad. In caring for these premature babies they had suggested that the obstetrician devote his attention to the baby before caring for the mother. In the winter the baby should be wrapped up and have hot water bottles placed about it, the temperature of the water in the bottles being 102 to 104° F. He did not favor the plan of wrapping the baby in cotton unless an accurate jacket could be

made as it was hard to get at a baby when it was simply wrapped in cotton. He found ordinary baby clothes or the leg of woolen underdrawers a more convenient form of clothing. It was most important to keep the temperature of the entire room warm, that was at a temperature of 77° to 85° F. This was all that was required no matter what kind of a room or what kind of heat was employed. The beautiful modern incubators were of course preferable, but the essential point was to keep the room at an even temperature and not to have eight or ten other people in the room; this last factor was most important. The child should have no one about it except when it was being cared for and in this way it would get enough oxygen for the necessary gaseous exchange. So far as the nourishment was concerned this involved the four questions, namely, what to give, how much to give, how often to give it, and how to give it. As the intestinal ferments were the same as those of the new-born infant it was unnecessary to give predigested foods or dilutions or breast milk. The preferable food for the premature baby was, of course, breast milk, and this one could usually get in the clinics, taking, if necessary, an ounce from one mother, one from another, etc., and thus making up the required amount. If breast milk was not available one was confronted with something of a problem, but would have to use cow's milk dilutions, and for these babies Dr. Kerley's evaporated milk had been found better than ordinary milk. Authorities differed as to the calories the premature baby needed. There was no question that the premature baby needed more than the ordinary baby, probably from 100 to 160 calories per kilo body weight. During the first week one could regulate the amount of food by the weight of the child, giving one-sixth or one-seventh the weight of the child in ounces. They usually began with 20 to 50 grams and went up one ounce a day as rapidly as they could. These premature babies were really still *in utero* and the impulse to grow was greater than that of a normal baby born at term. It was important to begin feeding the premature baby during the first twelve hours after birth. As to how often the premature baby should be fed, that question could not be answered. That was frequently a matter of the individual baby and the nurse who was accustomed to caring for such babies was usually able to arrange the intervals between feeding when the number of ounces to be given in twenty-four hours was determined. As to how to give the milk, if the sucking power was strong the baby might be given the breast or the bottle, but if it was not strong the Becker feeder might be used, and if the baby was unable either to suck or swallow the milk might be introduced through a catheter introduced either through the mouth or nose. Some premature infants had attacks of cyanosis. They should be made to cry for a time each day; during the attacks of cyanosis oxygen might be of help. A good intelligent, conservative woman to care for the baby was the most important factor in securing success. A child might be born at full term and still have the characteristics of a premature baby and require the care appropriate for a premature child. The last month *in utero* was a period of very rapid growth for the child and one during which great deposits of mineral salts were made. In premature babies they had found it advisable to administer mineral salts and iron.

Dr. DeWitt H. Sherman of Buffalo said there had been a call to save 100,000 babies in the United States this year and in response to that call the City of Buffalo had been considering what could be done. Where there were prenatal clinics and other organizations interested in child welfare work, as there were in some of the larger cities like New York, considerable could be done which was more difficult to accomplish in the smaller cities. But even in the larger cities there was a class of patients that was difficult to reach. The well-to-do and the very poor were well cared for but those of entremely moderate means who were able to employ only indifferent physicians did not receive as good care as the very poor. How to reach the medium class of people was a very complicated problem because the physician who was caring for them did not wish to be interfered with and at the same time he was a danger either on account of his indifference or his lack of education. As to how these men could be reached, he knew of no other way than through associations such as this. If organizations like the Pediatric Section of this Society were going to accomplish results something more should be done than merely to meet for a few days and tell what ought to be done; there should be a permanent committee to consider the problems and to make an effort to meet them as had been done in New York. They could then draw up a program to be sent to the smaller cities which would interest the men there and could be carried out by them. With such a program the cooperation of all the agencies in the smaller cities could be secured such as the local health department and welfare organizations. Dr. Griffith said that the only efficient galactagogue was the baby itself, and the speaker mentioned it because it should be emphasized so that physicians would encourage mothers to try persistently to nurse their children since determination was a very important factor in success. There was one modification of breast feeding worth considering. If one had a cross, colicky baby, passing curds, gas, and mucus in increasing amounts it was probably due to carbohydrate fermentation and contributing fatty acid fermentation, and a great deal could be done by using a powdered casein mixture sweetened with granulated sugar. Dr. Schwarz laid emphasis on the temperature and food, but there was a third element which he did not bring out strongly and that was with reference to handling premature babies. They should be wrapped up and no attempt made to dress them.

Dr. E. Gustave Zinke of Cincinnati emphasized the importance of the scientific and practical care of the pregnant woman from the day of conception to the end of term. The obstetrician who had the care of a pregnant woman was like the captain of a trans-Atlantic steamer. One could not imagine a captain taking charge of such a ship at the moment of its departure. He took charge of his ship long before the time of sailing and learned everything there was to know about it and the obstetrician should know his patient before she comes to labor, and the only way this could be accomplished was by having her come under his attention early. He should know her general health, her pelvic capacity, and the position of the fetus in the uterus. He should know beforehand what to anticipate and should prepare for it. People as a rule scarcely realize how much this meant and it was only in recent years that the value of proper scientific care during gestation had been appreciated. Such care should be given not only with the idea of saving the life of the mother and child but of coping with any complication that might arise at the time of delivery.

Dr. Charles Gilmore Kerley of New York, after congratulating the officers on the excellence of their program, said that Dr. Lobenstine had spoken of the influence of alcohol on the fetus and the new born and he wished to carry the statements a little further and speak of the influence that alcohol had on the developing child. They saw children lacking in inhibition readily excitable, with poor powers of concentration, and poor self control, who were brought to them for advice concerning what was called "nervousness," and they came from all sections of the country. Those children either in the first or second generation had a history of alcoholism. It was important to educate people to the fact that the taking of alcohol daily, even more than an occasional intoxication, rendered unstable the nervous system of the progeny. That was the result of the speaker's experience in years of observation. As regarded improving the breast milk of the mother, Dr. Kerley said his efforts in that direction had been a total failure. This was either because there was greater difficulty in building up the nursing capacity of the nursing mothers in New York or else because he did not know how to do it. He could check an excessive supply or correct one that was over rich, but he had been unable to improve the quality of the milk and agreed with Dr. Griffith on the subject of galactagogues. Regarding the care of premature babies, Dr. Schwarz had gone over the ground admirably. The giving of a high sugar content to make up the caloric value was a proper procedure and it was equally important to keep people away from the baby, not only for the reasons that Dr. Schwarz gave but because of the danger of infection. These premature babies had

a lowered resistance; a normal baby could overcome an infection that a premature baby could not withstand.

Dr. Anna White Marquis of Norwich said she was speaking as a woman for women. She had had a great deal of experience with women and they probably gave her more confidence than they would a male physician. The point she wished to make was that if men wished to have the birth rate raised there was just one way to do it. All the talking and writing of learned papers was in vain, the thing women wanted was to have the financial burden lifted. Many women wished to have a pregnancy interrupted because they could not afford to have another child and they went from month to month in constant dread of pregnancy, because they were unable to meet the financial burden and because it would mean suffering and neglect for the children already born. The financial burden should be lifted by having in every community a maternity hospital where these women could be cared for and some means established whereby their other children could be cared for in the home, during and after the confinement when the mother was unable to look after them. Every mother should have a bonus to pay for good nursing and for the care of the other children in the home and then the women would be willing to have children. We now had tuberculosis hospitals in every county and there was no reason why we should not have a maternity hospital in every county.

Dr. Eliza M. Mosher of Brooklyn spoke of a defect in the dress of women at the present time. She said she did not think it was realized that the dress of today was essentially different from that of a generation ago. The mode of dress at the present time gave no support to the breasts and this tended to lengthen the upper quadrant and to shorten the lower quadrant. It lengthened the veins in the upper part and shortened those in the lower part, and as a result the breast was being fed on venous blood and they all knew that a tissue fed on venous blood was not as well nourished as one fed on arterial blood, and this also applied to the milk ducts, which were lengthened above and shortened below. The mode of dress that permitted the breast to dangle without support crippled it during the developmental years and every doctor who had a young girl come to his office should advise her to wear a brassiere to prevent the downward pull. Another point Dr. Mosher emphasized was that Sir Arbuthnot Lane said that when he examined any woman for enteroptosis he always felt the breast and he nearly always found a lump in the outer quadrant of the breast in cases of enteroptosis. There seemed to be a definite relation between enteroptosis and the condition of the breast, and a very close one. The abdominal wall should either be developed so that it would form a proper support for the viscera or a proper support should be worn, for where there was enteroptosis the question of intestinal toxins entered into the problem and influenced the milk supply. Another factor in connection with the problem of infant feeding was the fact that during the early weeks after confinement the milk of the mother contained certain products of the internal secretions and when milk was pasteurized or boiled the products of the internal secretions were destroyed. Therefore she believed it was a mistake to pasteurize milk for infant feeding. In closing Dr. Mosher made a plea for the training of fathers, not only to a recognition of the necessity of giving pecuniary aid to the expectant mother but to help her in keeping a well-balanced mental condition. She thought the husbands should be reached and impressed with the fact that the responsibility for the welfare of the child rested with them equally as much as with the mother.

Dr. A. C. Mercer of Syracuse cited as an instance of the instability of the heat center in the premature baby, a case in which the child's temperature went to 110 F., and the only way it could be accounted for was that the water bottles were too hot, for as soon as the bottles were removed the temperature came down.

Dr. Schwarz of New York, in closing the discussion, said he had been able to get some reliable statistics with reference to miscarriages and stillbirths in the institution with which he was connected. They had the history of 10,000 families and of these 4,000 had been worked up and showed that in these 4,000 families there had been 17,000 pregnancies and 8½ per cent. of these had resulted in miscarriages, while over 2½ per cent. were stillbirths. These were taken from family histories in the general hospital and not simply from maternity cases. In speaking of the dressing of the premature babies he did not mean that when they were wrapped in cotton they were exposed but that the cotton was likely to become disarranged and it was harder to handle the children than when they were dressed in ordinary clothing and then wrapped in blankets.

Some Observations of the Chemical Examination of the Blood and Urine in Normal Pregnancy and in Toxemia of Pregnancy.—Dr. J. R. Losee of New York presented this communication which comprised the determination of the blood urea, creatinin and sugar, the carbon dioxide combining power of the blood plasma, the estimation of the total nitrogen, and the per cent. of it as ammonia and urea nitrogen of the urine. In addition, from these estimates they had determined the McLean index. After describing the method of collecting the specimens and the technique employed, the essayist said that the cases were all selected from the wards of the hospital and classified according to their clinical manifestations into four groups, normal pregnancy, preeclampsia, eclampsia, and pernicious vomiting. The normal cases were young primaparæ in the ninth month who were walking about and who presented no abnormal symptoms. The preeclamptics were women seven to nine months pregnant who were admitted with generalized edema, vertigo, eye symptoms, hypertension, and a large amount of albumin and many granular casts in the urine. The classification of preeclamptic was used in this connection for the want of a better name. The eclamptics were emergency patients who had had many convulsions, were comatose, and presented all the clinical features of this type of cases. The fourth group of cases were those of pernicious vomiting, comprising those from two to four months pregnant who came to the hospital with the diagnosis of pernicious vomiting. After a few days they were differentiated into the real and the pseudotypes of the disease. The total nitrogen of the urine was determined by the Kjeldahl method, and the urea and ammonia by the use of urease as described by VanSlyke and Cullen. The blood urea was also determined by the use of urease. The creatinin of the blood was estimated according to the method of Myers and Fine. The sugar concentration was estimated by the Lewis and Benedict method, and the carbon dioxide content of the plasma by the VanSlyke apparatus. It had been conclusively demonstrated in a former paper by Van Slyke and the writer that there was not an increase of amino acids in the blood in normal pregnancy or toxemia of pregnancy. The creatinin and sugar were practically the same as in normal patients. The carbon dioxide combining power of the blood plasma had already been shown to be below the average normal in a former paper by VanSlyke and the writer. The McLean index of urea excretion in this series was normal. Of the preeclamptic cases only four were examined, and it was found that the percentage of urinary nitrogen in the form of urea was definitely lower and that the urea nitrogen of the blood was somewhat higher than in normal pregnancy. Although the urea nitrogen of the blood was increased it did not seem sufficient to account for the low output or the gravity of the symptoms. The creatinin and sugar in the blood were normal, and the carbon dioxide combining power was the same as in normal pregnancy. The McLean index of urea excretion was lower than normal, and it would be observed from the tables that one week after delivery the index again rose to a normal level. In eclampsia the percentage of urinary nitrogen in the form of urea was much less than that found in normal pregnancy, and also lower than that found in cases of the preeclamptic type. It was of interest to compare the urea nitrogen figures in the blood of eclamptics and in the blood of interstitial nephritis with uremia. It was here that the chemical blood examination would help to confirm the diagnosis, for whereas in eclampsia there was a normal or slightly elevated urea nitrogen, in interstitial nephritis

and uremia the urea nitrogen of the blood would be from sixty to three hundred milligrams per one hundred cubic centimeters. The creatinin in the blood in eclamptics was normal, and in uremia it ran as high as thirty-three milligrams. In several blood examinations on eclamptics one case only showed a high urea nitrogen. This patient died and no autopsy was permitted. In the cases of pernicious vomiting a high ammonia coefficient was the only determination which was sufficiently abnormal to be of any assistance. The conclusions drawn from this study were as follows: (1) In the diagnosis of eclampsia a large amount of albumin in the urine and a normal blood urea were the most significant laboratory findings. (2) They did not know where the toxemia of pregnancy was formed, but they did know that neither nitrogenous products nor any other waste products could be held in the slightest degree responsible for the symptoms. (3) While modern biochemical technique was of great scientific interest and had a marked clinical value in some diseases, and while it had disproved such theories as the acidosis, the amino acid and the nitrogen retention as a cause of the toxemia of pregnancy, it afforded little assistance in the daily routine of obstetrics.

Dr. M. C. Breuer of Buffalo asked Dr. Losee whether he was familiar with Dr. Foster's findings. Dr. Foster claimed to have found a specific crystalline body which was the cause of eclampsia.

Dr. Losee replied that he was familiar with Dr. Foster's claim, but that no one else had been able to differentiate these nitrogenous bodies. There were still some 22 to 33 per cent. of undetermined nitrogenous bodies, and it might be that some of these were concerned in the production of eclampsia, but as yet nothing definite was known in regard to them.

Dr. E. Gustave Zinke of Cincinnati said that a paper like that of Dr. Losee should not be allowed to pass without discussion. All had recognized for a long time that there was a distinct difference between puerperal convulsions and uremic convulsions. In puerperal convulsions there was practically never any urea in the blood. In listening to Dr. Edgar's paper in the morning he had wanted to ask about a point on which Dr. Edgar placed considerable emphasis, namely, the prevention of eclampsia. Now when a man had a case of toxemia, with or without convulsions, which he had observed for weeks or months and that patient suddenly developed eclampsia, who was to blame? That remark reminded him of a very sad case in the early days of aseptic and antiseptic obstetrics. A thorough obstetrician and a prolific writer held the doctrine that no man had a right to lose a case because of puerperal fever, and that if he did he should be held responsible. This man lost a case from puerperal sepsis and committed suicide. Such radical statements ought not to go unchallenged. Perhaps the time would come when we could prevent toxemia and eclampsia in every pregnant woman, but that time had not yet arrived.

Two and One-Half Years' Experience with the Conservative Treatment of Eclampsia.—Dr. Ross McPherson of New York presented this communication. He said that after carefully studying the mortality statistics, both for mother and child, in the cases treated by the usual radical methods and comparing them with the results obtained by the more conservative methods, notably those reported from the Rotunda Hospital in Dublin, he began two and one-half years ago to test the value of medical treatment in the convulsive toxemias of pregnancy. This he did with considerable skepticism, since he had been brought up to consider the two words eclampsia and operation synonymous. These cases were in convulsions when first seen, and therefore a discussion of the etiology and prophylaxis of eclampsia had no place in this paper. No one was more convinced than the writer that careful prenatal treatment would eliminate the great majority of these cases. Careful observation of the pregnant woman, with routine blood pressure and urinary examinations, together with advice as to diet, clothing and ordinary hygiene, would prevent the occurrence of the greater number of cases of eclampsia that they now saw. There would always remain a certain percentage of physicians who would neglect this prenatal care, either on account of their lack of appreciation of its importance or on account of the failure of the patient to realize the gravity of the pregnant state. Therefore we should see, even under the most utopian conditions, a certain amount of this unfortunate complication. A thoughtful survey of the figures presented before the American Association of Obstetricians and Gynecologists, in 1917, in reference to the mortality from the surgical procedures employed in these cases, indicated the need of some other method of treatment. The writer presented the following: The cases were all pregnant and had had one or two more convulsions representative of the true obstetrical convulsive toxemias. Immediately after entering the hospital the patient's blood pressure was taken and a catheterized specimen of urine secured. She was then placed in an isolation room and as much quiet obtained as possible. One-half grain of morphine sulphate was given and the patient's stomach washed out. Two ounces of castor oil was then poured down the stomach tube at the end of the lavage. The patient was given a colonic irrigation of five gallons of 5 per cent. glucose solution. If the blood pressure was over 175 systolic, phlebotomy was done and a sufficient quantity of blood extracted to bring the blood pressure down to 150. Normal saline was not injected. It was unwise to bleed the patient if the blood pressure was lower than 175 systolic, because if for any reason a good deal of blood was lost during delivery the pressure might be reduced so low that the patient would die of shock. The same objection applied to the ante-partum administration of large doses of veratrum viride. The patient was then kept quiet and one-quarter of a grain of morphine administered every hour until respirations dropped to 8 per minute. At this time convulsions ceased and the patient usually fell into labor and could be delivered easily by median or low forceps. Sometimes a little ether might be given while waiting for the effect of the morphine. The convalescence was treated in the usual manner. In the writer's series of 67 cases, seven mothers died, a mortality of 10.4 per cent. Two of these mothers died before treatment of any kind could be administered, which brought the mortality down to 7.4. The number of children still-born in the series was 28.5 per cent., which was a considerable reduction over the best figures quoted. The writer felt that this method of treating eclampsia was a real contribution to obstetrical progress, and hoped that radically inclined obstetricians would give it a trial.

Is Cesarean Section Justifiable in Eclampsia and Placenta Previa?—Dr. George L. Brodhead read this paper, in which he first emphasized his belief that probably in a large percentage of cases of eclampsia and placenta previa abdominal section was unwarranted and unjustifiable. When the child was dead or not viable, when the patient was in active labor, with the cervix partially dilated or easily dilatable, and when the patient could not have the advantages of a well-equipped hospital, and the services of a competent surgeon, other methods of procedure might be not only more advisable, but absolutely indicated. On the other hand, increasing experience compelled him to believe that in a considerable number of cases cesarean section was the safest, easiest, and the most satisfactory method of treatment. The writer referred to his published statistics of 174 cases of cesarean operation in eclampsia from a large number of operators in various parts of the country (*American Journal of Obstetrics and Diseases of Women and Children*, Vol. LXXV, No. 5) in which there was a maternal mortality of 16.1 per cent., and said that in order to obtain more statistics he had reports of 39 hitherto unpublished sections which he gave in full. Of this series there were 35 primiparæ, 2 multiparæ, and in two cases the parity was not known. Six of the mothers died, giving a mortality of 15.4. Of the infants in this series only two premature infants died, a mortality of 5.8 per cent., which was a very creditable result. The last series of 39 sections gave a very much better infant mortality, 5.8 per cent., than the first series of 174, 18.8 per cent. Taking the two series together, there were 213 sections with 34 deaths, a mortality of 16.5 per cent. The writer presented these figures with a mind open to conviction, but at the present moment, he believed that the cesarean operation for eclampsia in primiparæ, at or near term, with a closed cervix, offered the best prognosis for mother and child.

He also reviewed the statistics of a number of authorities with reference to the maternal and fetal mortality, and compared them with those he had collected, much to the advantage of the latter. The writer also presented statistics of 48 hitherto unpublished sections which he had collected in response to a questionnaire recently sent to many obstetricians throughout the country. The maternal mortality in this series was 10.4 per cent. and the fetal mortality 10.8 per cent. The maternal mortality in this series seemed high, but excluding a case *in extremis* at the time of operation who would have died anyway, and one who died with chronic nephritis and chronic endocarditis, the mortality was 6.4. Excluding these cases and two other bad cases on the list the mortality was two per cent. In conclusion Dr. Brodhead expressed the opinion that cesarean section was of the greatest value in all patients at or near term, with central placenta previa, and in primiparæ at or near term with partial placenta previa and no cervical dilatation.

Dr. E. Gustave Zinke of Cincinnati said the practising obstetricians of today might be divided into three classes: First, those who pursued a strictly medical care of the convulsions, and who permitted the pregnancy to take care of itself, except in those instances in which the patient was already in labor, when they delivered without delay either by an easy version or by the use of low forceps; second, those who immediately proceeded to evacuate the uterus in every instance, no matter what the duration of pregnancy or the stage of labor, either by abdominal or vaginal hysterectomy, or by rapid dilatation of the cervix, followed by version and immediate extraction of the child; third, those who did not confine themselves to either of the foregoing methods but who, after considering every phase of the case, calmly sat in judgment upon it, giving special attention to the gravity of the symptoms, the period of gestation, the stage of labor, the patient's general condition, and, of equal importance, the patient's immediate environment. The practitioners of the first class were quite as wrong as those of the second class; there was but one difference between them, the former did much less harm than the latter. Obstetrical writers of extensive practical experience had for years spoken of three distinct clinical varieties of puerperal convulsions. The first variety was the so-called mild form, which always terminated in recovery, even when but little or nothing was done to check the progress of the disease. In these cases the convulsions did not ordinarily occur at short intervals, the pulse remained good, the temperature did not rise, and the urine in the bladder, though small in amount, was not highly colored, contained only a small amount of albumin and showed but few or no casts. The second variety included those cases in which the attacks were at once more frequent and prolonged, consciousness returned slowly after every seizure, the patient complained but little, the pulse though increased in frequency remained good and the temperature slowly but gradually rose after every convulsion. The urine was scant, dark and cloudy, and contained albumin and casts. These patients usually recovered under judicious medical care; surgical intervention did not improve the prognosis. Veratrum viride in fearless doses, high copious enema, stomach lavage, judicious hot baths or hot packs, gentle saline catharsis, and a milk diet were all that would be needed. It was true recovery might be expected if a skilled surgeon quickly performed an abdominal or vaginal section, but neither of these operations should be considered absolutely necessary or even desirable. In the third variety of puerperal convulsions the issue was invariably fatal, no matter what the treatment, medical, surgical, or both. From the beginning the convulsive seizures were so profound and prolonged as to leave the patient in a more or less comatose condition, consciousness did not return, and the patient passed from one paroxysm into another until death drew the curtain on the scene. In these cases abdominal section might save the life of the child if performed very early. The operation was justifiable only for this purpose. In all his dissertations on eclampsia for the past twenty years, the speaker had held that surgery had contributed little or nothing to the reduction of the maternal mortality of puerperal eclampsia, and that intelligent medical care had given the best results. Even if it were true that the same gratifying results could be obtained by abdominal or vaginal cesarean section as had been secured through the strictly medical care of puerperal eclampsia, the latter would still carry off the prize, because it excluded wounding, disfigurement, or maiming of the patient, while the medical treatment left no trace behind.

Dr. William Bryan of Staten Island thought that in well advanced cases of eclampsia it was best to turn the patient over to the surgeon and that cesarean section on such cases was preferable to any other operation. If one submitted these patients to any other operation than a cesarean section the mother or child or both would be lost.

Dr. William Pfeiffer of Brooklyn said that just before Dr. McPherson read his paper recommending the medical treatment of eclampsia before the Brooklyn Obstetrical Society he had had a case of eclampsia come into the hospital II para in convulsions. He did a cesarean section as soon as possible after the woman was admitted to the hospital and both the mother and child survived. Just after hearing Dr. McPherson's paper he had another case and decided to follow Dr. McPherson's method. After giving the morphine as Dr. McPherson described, labor did not begin. The convulsions ceased and then began again. He then thought the woman had suffered enough and did a cesarean section, which was followed by a stormy convalescence complicated with a psychosis, which might have been due to the toxemia, but that could not be proved, but he felt that if an early cesarean section had been performed the patient might have had considerably less trouble.

Dr. George L. Brodhead of New York congratulated Dr. McPherson on his figures and said he knew of no others as good as the ones Dr. McPherson had presented. He had no antagonism to the morphine method of treatment and thought that possibly a large number of cases might be treated by that method with good results. He had tried treating two cases by the morphine method and neither of them went into labor. He would like to know when labor did not come on what course Dr. McPherson would advise one to pursue. Dr. McPherson said that no baby alive before beginning the morphine treatment did not live after delivery. He would like to know what the mortality was during the first ten days after birth.

Dr. McPherson, in closing, thanked Dr. Zinke for his discussion and said that he agreed with him with the exception of one minor point. He had done 118 cesarean sections and one died, but not of eclampsia. He had been impressed by the fact that obstetricians seemed to be obsessed with the idea that the cesarean section was the proper treatment for almost every obstetrical complication and they seemed to have forgotten how to do anything else. Even the most enthusiastic operator must admit that the mortality from cesarean section was higher than that from normal labor and he was perfectly willing to agree with Dr. Brodhead that he would do a cesarean section in a case of eclampsia where it was definitely indicated. If a patient had a very large baby or a tumor obstructing labor he would operate as soon as anybody, but he could not see from the figures brought forward any reason for operating on every case of eclampsia simply because of the eclampsia. Dr. Pfeiffer's experience did not prove anything in regard to this method of treatment. A man might treat a considerable number of cases successfully and then have two disappointing cases within a few days. He did not want anyone to believe for a minute that he thought this method was applicable to all cases. One must take every case and analyze it and then apply the method that seemed best at the time the patient came under treatment. The general practitioner was the one who handled many of these cases of eclampsia and he should know when to give this treatment and when to stop it, and this was a plan he could follow when he could not operate. They were formerly taught that they should not give morphine as it dried up the body secretions. After giving morphine the blood pressure dropped and the patient passed more urine.

(*To be concluded*)

AN APPEAL TO PHYSICIANS IN BEHALF OF THE FOURTH LIBERTY LOAN.

BY JOHN JOSEPH KINDRED, M.D.,

ASTORIA, L. I., N. Y.

FOUNDER AND CONSULTING PHYSICIAN TO THE RIVER CREST SANITARIUM, ASTORIA, L. I., N. Y., AND TO THE BELLE MEAD FARM COLONY AND SANITARIUM, BELLE MEAD, N. J.

THROUGHOUT the long history of the evolution of man, we, as physicians and scientists, are impressed by the outstanding fact that even among primitive nations and races there has been intermittent striving toward government, and in the development of civilized governments a tendency to throw off the yoke of feudalism and tyranny and substitute some form of democracy and popular government in the interest of the masses of people, as opposed to the autocracy of the classes, as it exists in Germany, and the nations, like Turkey, in unholy alliance with her in the present world war.

This phase of the evolution of man, amply set forth by Herbert Spencer, John Stuart Mill, Charles Darwin, Edward Russell Wallace, and others, in a sociological and political, as well as in a purely scientific sense, is of such interest from the physician's viewpoint, and suggests such surprising lack of political and moral evolution in Germany, that this article is presented somewhat from the viewpoint of a racial evolutionary study as well as in the sense of trying to help in a practical way the successful floating of the fourth liberty loan, the campaign for which is now on.

As examples of the social and political evolution (and revolution) referred to as showing the trend toward democracy and the throwing off of the yoke of tyranny and autocracy (out of which last-named tendencies Germany has not yet begun to evolve, if the Von Tirpitz and junker policies of frightfulness and annexation are to continue as national policies), the most notable are the French Revolution, the American War of Independence, and similar movements in England resulting in the granting of the Magna Charta in the thirteenth century, the beheading of Charles the First in the seventeenth century—all in the direction of greater personal freedom and more democratic or representative government by the masses of the people.

This tendency toward this kind of political, moral and social evolution has not appeared in Germany, having been completely stifled by the feudalistic, autocratic, arrogant supremacy of her military ruling castes. Throughout the world, among all races and creeds, there has gradually evolved an opposing sentiment to Germany's policies, based on her failure to go forward in the natural processes of political, moral, and social evolution—an opposing sentiment which now finds expression against Germany and her allies, according to the psychology and temperaments of the races and nations arrayed against her.

The United States having never entered upon or engaged in an unrighteous or unsuccessful war, must not be placed for a moment in the position of faltering in winning the present war because of the lack of ample money to back to the limit our brave and unselfish men in the army and navy, now in a death struggle with the hordes who would destroy every American ideal and the foundations of a possible world peace, founded on democracy and international justice, the highest ideals for which the world can fight.

The present war is not America's first bitter fight for human rights and national and international righteousness, nor is it the first war for this sacred cause in which others of the Allied nations have engaged, but this war is the most vital and important in which practically all the civilized nations of the world are at war with Germany, which is in itself significant, and portending one result—victory for democracy and civilization over autocracy, feudalism, and barbarity.

German military megalomania, propaganda, and ruthlessness, all too clearly show in this struggle that the issue is: shall so-called German *kultur*, or democracy, survive? And we, as loyal citizens of a mighty republic, now the greatest world power, have the solution of this vital question in our hands in that we must finance the war; and it is far better that the whole or the greater part of the sum called for in this loan should be contributed for the coming issue of Government liberty bonds by the great masses of the American people than by the banks and financial institutions, so as to leave the last named free to use their capital chiefly in extending credit and stabilizing normal and war business in other necessary directions.

It is hardly necessary to point out the importance to us, as citizens, enjoying the high privileges and the corresponding serious obligations of citizenship, in the greatest and most advanced republic in the world, of making this fourth loan a signal success, because of its effects on us individually and on the fighting spirit of our boys "over there," and also on our nation, our allies, and the enemy nations.

The effect on us individually of buying liberty bonds, to our utmost ability in the use of both all available cash and all available credit, is first, as a cold business proposition, that these bonds are the soundest, safest and best investment that will be offered, even in these days of low-selling securi-

ties, and their purchase by us helps us individually, because it helps us to save money, strengthens our credit, educates us along financial, thrift, economic, and political lines; it provides us the opportunity to do patriotic and civic duty and to consider community, national, and international benefits as related to ourselves; it teaches us the value of coordinated effort in the nation as a unit in war and in business; it is a wholesome stimulant to our moral natures as men and women; it, above all, emphasizes the part taken by ourselves in protecting and sustaining our dear ones and our brave compatriots who are fighting our battles to make the world a more decent place in which to live.

One of the leading purposes of this liberty bond sale, as in previous sales, is one that specially appeals to physicians and humanitarians—to humanize the war through the further perfecting and augmenting of the already wonderfully efficient medical department and the supplying of all necessary comforts to the soldiers, both the sick and the well.

The success of the fourth liberty bond sale is highly essential to further impress our Allies with the idea of our own strong belief in our high American principles and ideals, and that we consider that they have all, by implied consent, recognized these high principles of American democracy as a higher basis for an improvement along these lines in the countries of our Allies, thus carrying the best inspiration to every fighting unit against Germany. It is inconceivable that we, as American citizens, could by any possible indifference to this momentous matter fail to subscribe and oversubscribe this loan at this critical time, in such a prompt manner as to impress our Government with our loyalty and earnest support, and our enemies with our protest against their barbarous conduct and policies.

It is an axiom that governments need money in large amounts to carry on war, particularly this gigantic world war, in which the chief issue is organized Prussian militarism set up against the rights of small and helpless nations, inspired by the fiendish philosophy of Nietzsche and Treitschke, and the thought that barbarous brute force and might make right, or at least would make for world dominion by the morally insane leaders of German propaganda and military caste, who dreamed only of bloody conquests, in violation of all international decency and the recognized rights of sovereign, weaker peoples.

Napoleon the First truly said that "an army traveled on its stomach," in the sense that the best fed, equipped, and trained army would, all things being equal, surely win victory. Our own country and our Allies have already spent billions of dollars and thousands of precious lives to overcome Germany's menace to our national rights and the world's civilization; and in the drafting and organizing in record time of the American army, soon to be one of the most effective of the armies in Europe, this nation has made untold sacrifices, and will make further sacrifices. It is obviously a most urgent necessity to continue to support and augment this army at home and abroad, in order to end the war as quickly as possible, and thus save lives, as well as the sacred cause at stake; it is equally urgent that the United States shall, regardless of the cost measured in mere dollars, continue to feed, supply, and fully equip this army in the most efficient manner possible.

To this end, and to the end that we may fully and loyally support our Government in its efforts to bring about a lasting world peace, founded on true democracy, the assured rights of weaker peoples, and guaranteed international righteousness, let us buy liberty bonds to our utmost ability, both for cash and on the very liberal installment plan offered by the Government and the banks.

CANCER: ITS CAUSATION AND PREVENTION.

BY JAMES W. SHANNON, M.B.,

SAN DIEGO, CAL.

It is common knowledge that water contains various kinds of living microscopic organisms, some of which, as, for example, typhoid and cholera bacilli, are recognized as the cause of disease; by far the greater number, however, have, without sufficient reason, heretofore been regarded as harmless, and have been and are still being applied to all parts of the body externally, and consumed internally, in enormous numbers, in ignorance of the serious dangers to which it is now certain they give rise.

There is abundant evidence to prove that the essential cause of cancer and all other forms of new growth, or tumor, is one or many species of those microscopic organisms which are commonly known as the "Protozoa." More than thirty thousand species of protozoal organisms have already been defined, and it is probable that many others yet remain to be discovered; hence the isolation of one or more species or organisms concerned in the causation of cancer is of little practical value, since the possibility that others remain undiscovered cannot be excluded.

The growth of protozoal organisms is governed by various conditions, among which only the following require to be considered in this connection, namely: sunlight, movement, temperature, and food material.

Sunlight is favorable to the growth of protozoal organisms, and hence they are present in all surface waters. In ground waters, if they exist at all, they are usually only to be found in comparatively small numbers.

Quiescence or stagnation is a necessary condition for their highest development, and for this reason they are to be found in the greatest numbers in reservoirs, ponds, and small lakes. It will be seen later that in connection with these sources of supply the association of water with cancer reaches its highest degree. Water kept in movement by gravity and wind action, as in rivers and great lakes, tends to retard the growth of protozoal organisms, doubtless by causing their dispersion and interfering with their food supplies.

Temperature affects the development of protozoal organisms through its influence upon the viscosity of water, high temperature lowering the viscosity and low temperature raising it. Low viscosity interferes with the ability of protozoal organisms to float, and as they are unable to thrive except at or near the surface, their numbers are small in the warm water of the tropics as compared with those of temperate or frigid climates.

Nitrogenous materials form the food supply of protozoal organisms, hence their numbers tend to be

large in waters containing much decaying animal or vegetable matter. Some reservoirs are especially liable to become foul for this reason, and in these the excessive growth of protozoal organisms is frequently a source of serious trouble. The development of organisms is also unusually abundant and rapid in ground waters containing large quantities of nitrogenous matter when exposed to sunlight in reservoirs at the surface.

According to the numbers of protozoal organisms, as determined by the foregoing conditions, it is possible to distinguish the following classes of water: (1) Stagnant water (reservoirs, ponds, small lakes), protozoal organisms present in highest numbers; (2) water in movement (rivers, great lakes), protozoal organisms present in moderate numbers; (3) tropical waters, protozoal organisms in fewer numbers than in the preceding classes; (4) ground waters (wells, springs), protozoal organism few, frequently absent.

Accepting tentatively the view that protozoal organisms are the ultimate cause of cancer, it is obvious that the distribution of the disease should be expected to correspond with the character of the water supplies as determined by the numbers of protozoal organisms present in them. Thus, for example, communities supplied with water from reservoirs are exposed in a greater degree to the influence of protozoal organisms than those using the waters of wells or springs, and should therefore be expected to suffer accordingly from cancerous affections. For the same reason it is also to be expected that the highest incidence of cancer should fall upon those parts and organs of the body to which the regular application of water is a normal event, and that the disease should be rarely manifested in parts which are only liable to accidental contact with water. These considerations open to view a large field of inquiry hitherto unexplored, which it is the present purpose to investigate by means of the statistical and other data now available. Such an investigation, since it concerns the relation of water to cancer, cannot fail to result in conclusions of definite theoretical value, and in the event that a causative relation is established between water and cancer, in indications of enormous practical importance in the control and prevention of the disease.

Mortality from Cancer in the Cities According to Latitude. 1908-1912.

No. of Cities.	Degrees of Latitude.	Rate per 100,000 Population.
35	60 N. 50 N.	105.7
48	50 N. 40 N.	92 4
24	40 N. 30 N.	78.1
7	30 N. 10 N.	42.3
4	10 N. 10 S.	40.9
7	10 S. 30 S.	37.7
5	30 S. 40 S.	89.8

Statistical research has rendered it possible to define the broad outlines of cancer distribution over the surface of the habitable world, and, in civilized countries, where the data are more complete, to distinguish in somewhat minute detail the differences which exist between States, cities, and localities. The most notable feature of cancer distribution throughout the world is the regular manner in which the disease prevails according to latitude. The above table from Dr. Frederick L. Hoffman's extensive work, "The Mortality from Cancer Throughout the World" establishes this clearly.

It is impossible to believe that the uniformity which characterizes these figures could exist unless the distribution of cancer were governed in a systematic manner by one or more of the great forces of nature, acting, not upon individuals, but upon the causative agent of the disease. For the present purpose it is sufficient to observe that the correspondence between cancer prevalence and latitude implies an equally definite relation between cancer prevalence and temperature. In effect, therefore, the foregoing table may be interpreted as showing the influence of temperature upon cancer causation, and in view of this it becomes of the utmost importance to recall the fact, already mentioned, that the development of protozoal organisms is also influenced by the action of temperature upon the viscosity of water. Independent observations in various parts of the world have also established the fact that in the cold waters of arctic and temperate climates the density of living organisms at the surface far exceeds that of the warm waters of tropical regions.

Since the distribution of both protozoal organisms and cancer is thus governed by temperature, and since it is contrary to theory and the verified facts of cancer causation to believe that cancerous manifestations are a direct result of the action of temperature upon the tissues of the body, it becomes logically certain that a causative relation must exist between protozoal organisms and cancer. It follows, then, in the face of such a relation that the prevalence of cancer must vary according to the development of protozoal organisms; or, in other words, that protozoal organisms are a determining or causative factor of the disease. For the present it is sufficient to notice that this view is entirely consistent with the statistical facts of cancer distribution in its widest aspect; later it will appear that it is also consistent with every other feature of cancer causation.

The principles of cancer causation are obscured by a number of predisposing conditions, such as age, sex, occupation, etc., none of which are of fundamental importance, but which, nevertheless, tend to influence the incidence of the disease upon any community. In order, therefore, to perceive clearly the fundamental causative principles it is necessary to eliminate from consideration all such unessential factors, and to assume for a time that all populations are predisposed to the disease in an equal degree. On fundamental grounds, then, the theory that protozoal organisms are the ultimate cause of cancer demands that the disease should prevail according to the character of the water supplies of each community, as determined by the number of protozoal organisms present in them.

By reason of the fact that the development of protozoal organisms is favored by quiescence or stagnation, and retarded by movement, and since waters are caused to flow or to stagnate according to the physical characters of a country, it is obvious that the prevalence of cancer in various localities must be governed in a large measure by the topographical features peculiar to each. It is therefore to be expected that cancer should prevail more abundantly in lake districts, valleys, and low-lying coun-

try, than in mountainous regions, or in the neighborhood of rapidly flowing rivers or streams. If the facts of cancer prevalence are interpreted in the light of these considerations, the relation of the disease to the water supplies will then become apparent. The material for such an inquiry is unlimited, and for the present it is only possible to consider certain features of the subject which are prominent in the records of cancer in the United States of America.

Statistics covering any period of years show that both the maximum and minimum incidence of cancer is invariably associated with the same group of States or region of the country. The degree to which this is true renders it virtually certain that the character of the country has a determining influence upon the prevalence of the disease in each part. If the States included in the United States registration area are arranged in order of cancer prevalence it will be found that they fall together into groups in a manner almost identical with the geographical arrangement. This is illustrated by the following table showing the States having the maximum and minimum rates of cancer mortality for the period 1913-14-15, according to the figures of the United States Bureau of the Census:

Maximum and Minimum Rates of Cancer Mortality per 100,000 of Population of States in the U. S. Registration Area for the Period 1913-14-15.

	1913	1914	1915
Average throughout registration area	78.9	79.4	81.1
Vermont	111.7	109.9	104.0
Maine	107.5	107.6	106.6
New Hampshire	104.4	100.8	109.4
Massachusetts	101.4	101.2	104.0
California	97.6	97.9	98.1
Rhode Island	93.3	91.2	92.1
New York	87.8	90.0	92.0
Connecticut	85.1	86.5	92.6
Washington	53.5	61.9	57.2
Utah	52.1	45.8	48.3
Colorado	50.7	58.3	53.4
Montana	49.4	51.5	50.0
Virginia	48.4	48.9	53.7
Kentucky	48.0	46.0	49.7
North Carolina	47.9	57.8	59.5

Study of this table will show that, with the exception of California, the arrangement of these States according to the figures of cancer prevalence places each in its correct geographical position with respect to the others. Three groups may be distinguished as follows: (1) a group comprising all the States of New England and the State of New York, which except for the interposition of California would appear in unbroken sequence; (2) a group hereafter referred to as the "Rocky Mountain" group, which consists of the States of Washington, Utah, Colorado and Montana; (3) the "Appalachian group" which includes the States of Virginia, Kentucky, and North Carolina.

It will be seen that while there is no substantial difference between the rates of cancer prevalence in the States of the Appalachian and Rocky Mountain groups, there is a most striking difference between these and the New England group. In estimating its importance it must be realized that this difference is not an exceptional or variable occurrence, but is a constant feature of cancer prevalence, and presumably, is therefore due to some permanent influence which is more potent in the States of New England than in the region of the Rocky Mountain and Appalachian Systems.

A distinguishing feature of the landscape is the extraordinary number of lakes in New England and the northern part of the State of New York; the State of Maine alone has more than fifteen hundred, and throughout the States of New England, out of a total area of 66,424 square miles, 4448 square miles consist of water. Such an enormous area of water, in the form of comparatively small lakes, must necessarily allow of abundant opportunities for stagnation, and consequently tend to favor the maximum development of protozoal organisms. In view of this and of the fact that this region is associated with the maximum degree of cancer prevalence, there is a strong presumption that water and protozoal organisms are factors in the causation of the disease.

The influence of the physical characters of the country upon the behavior of water, on the States belonging to the Rocky Mountain and Appalachian groups, is such as to reduce the possibilities for stagnation to a minimum. These states include within their boundaries portions of the two great mountain systems of the North American continent, and therefore form part of two great water sheds draining towards the Mississippi Valley in the center and the eastern and western coasts on either side. The number of lakes throughout these states is small in comparison with that of the states of New England, and owing to the fact that the country may be broadly regarded as a series of plateaus or terraces rising towards the summit of mountains of considerable height, the flow of water under such conditions must necessarily tend to be for the most part rapid, and hence generally unfavorable to the development of protozoal organisms.

The minimum degrees of cancer prevalence thus occur in districts which afford the smallest opportunities for the stagnation of water, and, as in the case of the maximum degrees of prevalence, the facts concerning them are entirely consistent with the view that water and protozoal organisms are factors in the causation of the disease. When the details of this part of the subject are carefully weighed, and their meaning as a whole attentively considered, their significance can hardly fail to be regarded as having the value of proof; otherwise it is impossible to conceive that a relation of the kind established could exist if protozoal organisms and water were not influential in the causation of the disease.

The increasing tendency for cancer to prevail according to the progress of modern civilization is a subject of great theoretical interest to students of the disease, and of considerable anxiety to those responsible for its control. In less than the lifetime of a generation the mortality from cancer in America has increased by at least 25 per cent., and under existing conditions threatens to advance still further. In endeavoring to understand this feature of cancer prevalence, attention is arrested by the fact that the present-day facilities for travel, together with the demands of commercial and social life, have not only resulted in a great permanent increase of the urban population, but also, by attracting a larger proportion than formerly of the rural population to cities, have tended, in some measure, to equalize the conditions of urban and rural life. By reason of the fact that the rate of cancer prevalence in cities is constantly higher than in rural districts, the general

result has been the exposure of a greater proportion of the population to an increased risk of acquiring the disease.

In reality the progressive increase of cancer is more precisely due to urbanization than to civilization, and since urban populations are predisposed in a special degree to cancer, it becomes important to consider those conditions peculiar to city life which may influence the causation of the disease; prominent among such conditions is the character of urban water supplies.

The needs of urban populations require that the water supplies of cities should be stored, usually for a considerable time, in reservoirs, under conditions which generally are highly favorable to the development of protozoal organisms. Hence, notwithstanding the use of methods for its purification, water in cities, as delivered to the consumer, is, by reason of the numbers of protozoal organisms present, less desirable, from the viewpoint of the theory of cancer causation herein suggested, than the average water from natural sources used by rural populations and primitive peoples.

There is much evidence to support the foregoing views of cancer causation, but before attempting to render its full significance clear it is necessary to outline certain principles underlying the nature of the disease; these are as follows: (1) that cancer and other neoplasms are individual new formations, developing independently of the body in which they exist by virtue of a degree of vital energy which is inherent, and peculiar to their cellular elements, and which is also of higher potency than that of the cells of normal tissues; (2) that cancerous and other neoplasms originate from normal tissue-cells by virtue of and according to the fundamental principles which determine the origin and growth of all living organisms; (3) that, similarly to all living organisms, cancerous and other neoplasms result from the union of male and female nuclei according to the laws which govern the process of fertilization; (4) that the male and female elements concerned in the procreation of cancerous and other neoplasms are, respectively, certain fertilizing agents arising from various species of protozoal organisms in water, and the normal cells of epithelial, glandular, and connective-tissue structures.

The nature of cancer is therefore that of a hybrid organism resulting from heterogeneous fertilization between the male elements of protozoal organisms and the normal cells of certain tissues of the body. Since this view of the disease involves considerations too numerous for discussion within the limits of this article, it must suffice for the present to state that it is entirely consistent with the accepted principles of biological, pathological, and physiological science.

In order to permit access of fertilizing elements to the living cells of the tissues, it is necessary that a defect or lesion of the epithelial surfaces of the skin and mucous membranes should exist. Clinical observation has shown that cancer manifests itself at the site of preexisting or "precancerous" lesion, and authorities are generally agreed that such lesions are a prominent feature in its causation. Theoretically, cancer cannot arise in the absence of a lesion, nor in the absence of water, protozoal organisms, and their fertilizing elements; hence it is certain that four factors are esssential in the causation of the disease, which are as follows: (1) Fertilizing elements. (2) Lesions exposing living tissue cells. (3) Protozoal organisms. (4) Water.

Now, since the causation of cancer is dependent upon the cooperation of all these factors it is obvious that the disease may be prevented by the elimination of any one. But further, since the cooperation of these factors is determined by many conditions, both favorable and adverse, some of which concern the character of water with respect to the living organisms contained in it, and others the condition and environment of communities and individuals, it is evident that the distribution and prevalence of the disease must vary in accordance with the manner in which such conditions combine to influence any of the factors, or their cooperation as a whole.

Three of the factors of cancer causation, namely, the fertilizing elements, protozoal organisms, and water are related to each other in such a way that for practical purposes they may be included in the considerations which concern water only. The remaining factor, lesions, is independent of the others in all respects except those which relate to the causation of cancer. Hence the subject resolves itself into an inquiry concerning the manner in which the manifestations of cancer correspond with the conditions which determine the application of water to lesions. The statistical records of cancer afford a safe basis for inquiry along these lines; it is therefore proposed to consider certain statistical facts of the disease in the light of the principle that contact of water with a lesion is essential in its causation.

The incidence of cancer upon parts and organs of the body, as recorded by the United States Bureau of the Census for the year 1915 is as follows:

	Rate per 100,000 Population.	Per Cent.
Cancer and other malignant tumors (aggregate)	81.1	100
Cancer of the buccal cavity	3.2	3.9
Cancer of the stomach, liver	31.5	38.9
Cancer of the peritoneum, intestines, rectum	10.9	13.4
Cancer of the female genital organs	12.1	14.9
Cancer of the breast	7.7	9.5
Cancer of the skin	2.9	3.6
Cancer of the other organs and organs not specified	12.9	15.9

This table shows that cancers of the alimentary system constitute 56.2 per cent. of all manifestations of the disease; those of the female breast and generative organs together 24.4 per cent.; and those of the skin 3.6 per cent. These parts together are only a small portion of the total mass of the body, yet they bear 84 per cent. or nearly seven-eighths of the weight of cancer incidence. This disproportion will, however, appear much greater when it is remembered that in each organ certain limited areas, as for example the pylorus, cervix uteri, or the skin of the face and hands, are specially favored as the seat of the disease. In view of this it seems impossible to conceive of cancer as otherwise than a local affection, arising independently of metabolic or constitutional disturbances, from causes limited in action to parts specially predisposed to lesions by reason of exposure to various external influences.

Returning to the consideration of water and lesions as causative factors of cancer, it is obvious that the chances of the disease originating at the site of any lesion must vary according to the frequency and duration of its contact with water. It is therefore to be expected that cancer is most likely to arise in those parts of the body to which the application of water is most frequent, or from which its removal by the ordinary processes of drying, or by evaporation is difficult or impossible; and conversely, that cancer should prevail in the minimum degree in those parts of the body to which under normal circumstances water is never admitted. It remains to be determined how far these expectations agree with actual facts, and it is therefore proposed to select the stomach, uterus, breast, and skin to illustrate the relation of water and lesions to the disease in organs with a high rate of cancer incidence, and the lungs and respiratory passages as an example of the rarity of the disease in parts which, normally, are never exposed to contact with water.

It has been estimated that the stomach is attacked by cancer three times more freqeuntly than any other organ, and that cancers of the stomach constitute one-third of all cases of the disease. Cancer may arise in any part of the stomach, but it is highly significant that the region of the pylorus—the most frequent site of ulceration—is attacked in overwhelming proportion to the other parts. It is also very significant that the liability of males and females to gastric cancer differs in a degree which exactly corresponds to the sex-liability of gastric ulceration. Dr. Frank Smithies has shown by analysis of a long series of consecutive cases that the sex ratio both of gastric cancer and gastric ulcer is as 2 to 1 for males and females, respectively; since it is impossible to conceive, except on the basis of a relation between ulceration and cancer, that this sex ratio could remain constant, its value in showing the importance of lesions in the causation of the disease can hardly be exaggerated.

Concerning the part played by water in causation of gastric cancer it is sufficient to observe that all water necessary for the physiological requirements of the body is received into the stomach, and retained therein for a longer period than in any other parts of the alimentary system. Although an equal quantity passes through the mouth, pharynx, œsophagus, and doubtless through the duodenum, its contact with these parts is of comparatively short duration, and the opportunities for fertilizing elements to gain access to exposed tissue cells are consequently much less favorable. Having regard therefore to the presence of lesions, and the relations of water to them with respect to volume, frequency, and duration of contact in various parts of the alimentary tract, it is of the highest significance that cancer should prevail in the maximum degree in that part, namely the stomach, which by the nature of its function must necessarily favor the most intimate association of water with lesions.

The uterus ranks second in order of cancer incidence, its liability to attack being estimated at about one-third of that of the stomach. Cancer may arise in any part of the female reproductive system, but the proportion in which it manifests itself in the uterus, and more especially in the cervix uteri, so far exceeds that of all the remaining parts together as to render it virtually certain that local conditions peculiar to the cervix uteri are influential in determining the disease. Without entering upon a discussion of gynecological matters it is sufficient to realize that ulceration, erosion, laceration, and other lesions of the cervix uteri prevail to a degree which exceeds that of any other region in the body of equal size. For very apparent reasons married women suffer from such affections in greater proportion than the unmarried, and in this connection it is important to observe that the incidence of cancer upon the uterus is higher among the married than in those who are single.

Water is not functionally necessary to the female generative organs, and therefore its presence in any part of the genital tract is an abnormal event. The deliberate use, however, of water as a routine measure of cleanliness, to prevent conception, as a prophylactic against infection, and, especially, in those suffering from uterine lesions, to relieve objectionable discharges, is general throughout a large section of all civilized populations. Also there is reason to believe that water may be admitted to the genital tract in the course of ordinary bathing, particularly in women whose muscular mechanism is relaxed by age, or impaired by obstetrical, or other forms of injury.

The removal of water from the generative organs by evaporation, or any ordinarily available means, is impossible, and hence, although only a small quantity is retained, the time during which it remains in contact with the mucous surfaces is very prolonged. Since the chances of fertilization occurring must necessarily vary according to the length of time fertilizing elements remain at the site of a lesion, it is clear that the conditions in the genital tract are highly favorable to such an event, and consequently to the causation of cancer in a manner and degree consistent with the theory herein suggested.

Cancers of the breast vary in type, and in the details of their causation, according as to whether they originate from the cells of the lactiferous ducts and glandular structures, or from those of the skin-coverings and connective framework of the organ. The causation of cancer in the skin and connective-tissues of the breast, differs in no essential respect from that of similar manifestations in other parts of the body, and therefore does not require to be specially considered. The causation of true mammary cancer is, however, exceptional with respect to the manner in which the cells of the glandular tissues and ducts are exposed to contact with water, and in order to appreciate the reasons for the marked liability of these parts to the disease, it is necessary to consider certain anatomical and functional peculiarities of the organ.

The breast is the only example of a large glandular organ opening directly upon the surface of the body. The lactiferous ducts, fifteen or twenty in number, converge toward the nipple, and open by the numerous orifices upon its summit. The skin of the nipple and its areola differs from that of all other parts except the eyelids, scrotum and analogous female structures (all favorite sites of cancer), by reason of its thinness and delicacy of texture, its tendency to be thrown into folds or

wrinkles by involuntary muscular contraction, and the tuberculated or warty character of its surface at the summit of the nipple—all of which features favor the retention of water. Owing to the absence of definite muscular control, the lactiferous ducts may be regarded as open channels which offer little or no resistance to the passage of fluids in either direction. The substance of the breast is loose and spongy; capable of expansion, and of accommodating a considerable quantity of fluid. At the age when reproductive activity ceases the breast rapidly undergoes atrophic changes, as a result of which a condition of extreme relaxation and flaccidity is produced; it is not difficult to believe that the entrance of fluids is thereby facilitated.

Having regard to the fact that milk may flow passively from the lactiferous ducts, it is justifiable to assume that there is little or no resistance to the passage of fluids in the opposite direction, that is, from without inward. In the case of water containing protozoal organisms it can hardly be doubted that the faculty of locomotion which characterizes most fertilizing elements must be of considerable assistance in enabling them to reach the cells of the glandular tissues. In view of these considerations it is justifiable to believe that in the course of bathing, water may enter the lactiferous ducts by the force of capillary action, external pressure, or suction, and so be carried to the deeper parts of the breast substance. Having once gained an entrance it remains in contact with the tissue-cells for the longest possible time.

Independently, however, of the foregoing there is evidence of a conclusive kind to convict water in the causation of mammary cancer. This evidence refers to the relation of the mortality rate from cancer of the breast in Japan, to the customs of the Japanese with respect to the use of water in bathing, as contrasted with the corresponding mortality-rates and customs of other countries. For reasons which will appear later it is convenient to consider the mortality rate of the skin and stomach with those of the breast. The figures, as given by Dr. Frederick L. Hoffman in the work already mentioned, for Japan and the United States, are as follows:

	Japan, per 100,000 Population.		United States Registration Area per 100,000 Population.	
	Males.	Females.	Males.	Females.
Skin	0.9	0 6	3.5	2 1
Female breast		1 8		14 3
Stomach and liver	48.4	31.4	28 8	30 5

At first sight it will doubtless seem confusing to find that while the incidence of cancer upon the skin and breast is, respectively, about four times and eight times higher in the United States than in Japan, the corresponding rate for the stomach is uniformly lower. The problem therefore is to reconcile these apparently contradictory facts, in a manner consistent with the principles which are common to all other manifestations of the disease. At the outset it is obvious that the foregoing figures are inconsistent with any general or constitutional principle of causation, and consequently, that they can only be satisfactorily explained on the basis of differences in the relations of each part or organ to the causative factors of the disease in the United States and Japan.

The Japanese are notorious for their habits of personal cleanliness. It is a custom among them, carefully observed by every individual, irrespective of rank, age, sex, or condition, to bathe the whole body daily, and in this respect they differ from western races, in whom the use of a daily bath is for the most part restricted to a limited class of society. Apparently then the incidence of cancer in Japan and the United States, upon the parts exposed to water in bathing, namely the breast and skin, is directly the opposite of that which should be expected according to the view that water is a factor in the causation of the disease. The key to this paradox is found in the fact that not only are the Japanese careful never to bathe in cold water, but also that they have become habituated to temperatures far higher than American or European sensations could ordinarily endure. The bath is prepared in the evening by heating the water to a temperature of 113° F-115° F. This water is used in succession by every member of the household, including dependents. The process often requires several hours for its completion, during which time the temperature of the water is maintained at the point stated.

In estimating the effect of such temperatures upon the incidence of cancer it must be realized that the standards which apply to the bacteriological sterilization of water are, on the assumption that protozoal organisms are an essential factor in its causation, far in excess of those required for the prevention of the disease. Protozoal organisms are very sensitive to any change in their environmental conditions, and it is not probable that any species could survive exposure to a temperature so far beyond their power of adaptation as that of the Japanese bath. In so far then as protozoal organisms are concerned, the water used by the Japanese in bathing may be regarded as sterile, and therefore of no effect in the causation of cancer. In the light of this it is of the greatest significance that the most striking feature of cancer incidence among the Japanese, namely the extraordinarily low rate of incidence upon the skin and breast, is associated only with those parts of the body which are exposed to contact with water free in a special degree from living protozoal organisms.

The use of water for ablutionary purposes by Americans and Europeans is in direct opposition to the practice of the Japanese with respect to those details which are of theoretical and practical importance in the causation and prevention of cancer. Bathing of the whole body in America or Europe is not regulated as in Japan by national custom, and is therefore unsystematic and comparatively infrequent. There is an increasing tendency to encourage the use of cold baths, and in the case of warm baths water is seldom heated beyond, but usually below the normal temperature of the body; temperatures as used in Japan are virtually unknown. No care is taken to destroy organic life in water intended for personal uses, and there is no general aversion, as in Japan, against exposure of the body to contact with raw water.

In the light of the foregoing it seems to be definitely established that the incidence of cancer on the skin and breast is determined by those customs,

habits, or conditions which regulate the number of living protozoal organisms in water used for bathing. Since this is true in the case of the skin and breast, in America and Japan, it must also be true in principle for manifestations of cancer in other parts of the body, everywhere. In general therefore it may be stated that the maximum incidence of cancer is associated with the use, for personal purposes, of raw water, and tends to become reduced in proportion to the degree in which water is sterilized, or rendered more or less free from protozoal organisms by any other artificial or natural means. According to this principle, complete sterilization of water implies absolute protection against cancer; theoretically, therefore, cancer is a preventable disease, only the adoption of the necessary precaution can prove that it is so practically.

Cancerous manifestations in the skin present many other features of interest, but for the present it must suffice to consider briefly a few of the more prominent, with the understanding that the principles which apply to these are equally true in all other cases. Cancer may arise in any part of the skin, but those parts are attacked in undue proportion which are the seat of lesions, and are also most frequently exposed to water. The truth of this is apparent from the fact that the hands, arms, and face (which obviously are most exposed to lesions and water) are together affected more frequently than the whole of the remaining surface of the body.

On the face cancer tends to select the region of the orbit, the lips, and certain parts which, in elderly persons, are commonly the seat of seborrhoea, eczema or other diseases. The reasons for this are doubtless that in the region of the orbit the skin is extremely thin and delicate, and by its loose and wrinkled condition tends to favor the retention of water, the lips are specially liable to lesions from injury or disease, and are specially exposed to water in the act of drinking, and that water remain longer at the seat of seborrhoeic, eczematous, or other lesions, for the reason that the use of a towel in the ordinary manner is painful, and liable to cause further injury.

The undue incidence of cancer on the hands and arms is due to the fact that they are exposed to injury in a greater degree than any other part of the body. Special interest attaches to those cases in which the conditions of occupation not only predispose to lesions, but also demand the application of water to them as a routine proceedure. Prominent among such cases are "Paraffin Cancer" and "X-ray Cancer," and as these will serve to illustrate the variety of circumstances under which water and lesions combine to cause cancer, it is proposed to examine the salient features of each.

Cancer of the hands and arms is common amongst workers in paraffin, pitch, tar, and similar substances, first on account of the dermatitis induced by the irritant action of such chemicals upon the skin, and secondly by reason of the undue exposure of these parts to water, in the process of cleansing the skin thus injured. Difficulties arise from the fact that while thorough cleansing of the skin is important as a precautionary measure against dermatitis, substances like paraffin, tar, pitch, etc., tend to resist the action of water and are not easily removed even from healthy skin. When, however, the skin is inflamed and tender, it is necessary, in order to avoid pain and possible injury, to employ longer time and greater care in the manipulation of the parts. For similar reasons vigorous use of the towel is impossible, and hence the process of drying is apt to be incomplete.

With regard to the causation of cancer among *x*-ray operators it should be observed that the exigencies of this profession demand exposure of the hands especially to the action of *x*-rays in an injurious degree, and to water in the course of photographic work, and for the purpose of personal cleanliness. Many persons have sustained injuries of the skin from the action of the *x*-rays in the course of diagnosis and treatment, but there is no evidence to show, or even to suggest, that such injuries are associated with cancer in any special manner. While, therefore, it is virtually certain that *x*-rays alone are incapable of causing cancer, yet it is equally certain that they are an essential feature in the causation of that form of the disease which is limited to *x*-ray operators.

X-ray cancer is clearly determined by conditions of occupation, but there is no reason to believe that the part played by *x*-rays is fundamentally different from paraffin, pitch, tar or any other irritant in the causation of the disease. If, then, the action of *x*-rays is regarded as being limited to the causation of lesions, it becomes easy, on the basis of an association of such lesions to water, to reconcile the absence of cancer in some cases with its appearance among *x*-ray operators, and to perceive that *x*-ray cancer is governed by the same principles which regulate the causation of the disease generally.

In applying the principles of cancer causation suggested in the foregoing to those parts and organs of the body which are only very rarely the seat of cancerous disease, it will be found that in every case, either by reason of functional necessity or anatomical situation, such parts are shielded from contact with water. In the aggregate these parts far exceed in area or mass those which bear all but a small proportion of the incidence of the disease, and include the nervous, muscular, circulatory, respiratory, and genito-urinary systems, together with the osseous and connective-tissue framework of the body; that is, with the exception of the respiratory system, all those parts, which under normal circumstances, have no communication with the external world.

For certain biological reasons, which cannot be discussed at the present time, nervous and striped muscular cells are absolutely immune from cancer or any other form of new-growth. In the case of all other tissues immunity is only relative, and is determined by conditions which regulate their exposure to water. Cancer can, therefore, only arise in tissues other than those which constitute or communicate with the surface of the body as a result of a breach or lesion of the skin or mucous membrane; and such lesions may be due to injury or disease, but there is considerable significance in the fact that, clinically, sarcomatous growths are specially associated with injury. Also, since there is no reason to doubt that, by the application of water to such lesions, the causative agent of cancer, similarly to other microscopic organisms, may enter the blood-stream at the side of an injury, and be

carried from thence to a distant part of the body, the appearance of a sarcomatous growth in a part remote from the seat of injury is not theoretically inconsistent with the explanation herein suggested for other manifestations of cancer.

The lungs and respiratory passages are exposed to numerous bacterial and other influences which, especially in persons beyond middle age, tend to result in lesions and chronic irritation, probably to a greater degree than in any other part of the body, yet, notwithstanding this, cancer of the respiratory organs is an extremely rare event. Having regard then to the rarity of pulmonary cancer in the face of these conditions, it is clear that the disease cannot be altogether due to lesions, chronic irritation, or any of the external or internal influences to which the respiratory organs are normally, or frequently exposed; hence it follows that the causative agent of cancer is abnormal to, and only rarely present in the respiratory system.

In considering those foreign substances which may on rare occasions enter the respiratory tract as possible causes of pulmonary cancer, it is obvious that, since the disease cannot arise in the absence of its cause, no substance is entitled to consideration, unless its range of applicability is as wide as the distribution of cancer—that is, universal throughout the world; except water, no substance fulfills this condition.

A large quantity of water in the respiratory system is incompatible with life, and its presence in small quantities is a rare event. A small volume of water may enter the lungs as the result of accident, and water in the form of spray may be inhaled in the course of ordinary respiration. There is reason to believe that a considerable proportion of cases of pulmonary cancer are determined by conditions of occupation, but satisfactory data concerning such conditions are unavailable. For the present it is sufficient to observe that all the existing evidence is consistent with the view that water is concerned in the causation of cancer of the respiratory organs.

Hitherto the more prominent features of cancer causation have been considered independently and more or less disconnectedly, but in order to estimate the force of the conclusions which have been established it is necessary to realize that the same principles apply equally to all, and that by virtue of this they are capable of being united into a consistent whole. This united force possesses the logical value of proof, since it is inconceivable that in a matter of such complexity so great a number of diverse facts could be uniformly reduced to systematic order by any other principles than those governing the phenomenon of which each is a constituent part.

A study of the statistics of cancer and typhoid fever will reveal a relation between these diseases which, in any series of figures representing a sufficiently large area and population, is constant, but which by reason of the liability of certain factors to vary, more especially those concerned in the causation of typhoid fever, may be less apparent or altogether obscured in the statistical records of a limited population or locality. Further, it is well to remember in this connection that the statistics of disease are true in mass, but not in detail, and that any conclusions based upon figures representing limited areas are, therefore, open to dispute. The following table represents the broadest feature of the relation between cancer and typhoid fever; the figures are from the Mortality Reports of the United States Bureau of the Census:

Mortality of Cancer and Typhoid Fever Throughout the U. S. Registration Area for the Period 1900-1915, per 100,000 Population.

	1900	1901	1902	1903	1904
Cancer	63.0	64.3	65.1	68.3	70.2
Typhoid fever	35.9	32.3	34.3	34.1	31.7
	1905	1906	1907	1908	1909
Cancer	71.4	69.1	70.9	74.5	73.8
Typhoid fever	27.8	31.3	29.5	24.3	21.1
	1910	1911	1912	1913	1914	1915
Cancer	76.2	74.3	77.0	78.9	79.4	81.1
Typhoid fever	23.5	21.0	16.5	17.9	15.4	12.4

In view of the prevailing opinion that the reduction of typhoid fever mortality during recent years is due to the adoption of certain sanitary precautions, it is necessary, before attempting to supply reasons for the relation, apparent in the foregoing table, between cancer and typhoid fever, to emphasize the point that the problem of this relation is not directly concerned with the rise or fall in the mortality rates of these diseases, but deals solely with the manner in which these mortality rates vary toward each other. However satisfying any explanation for the decrease in typhoid fever mortality may appear to be when considered independently, the fact that a constant relation exists between cancer and typhoid fever demands that before such explanation can be regarded as acceptable, it must account for the corresponding increase in cancer mortality in a manner consistent with the facts of both diseases.

In addition to the foregoing table the inverse character of the relation between cancer and typhoid fever may be shown by any series of figures, representing large areas of population in which there is a notable difference between the maximum and minimum prevalence of cancer. The following tables, compiled from the figures of the United States Census Bureau representing the mortality of cancer and typhoid fever in the States of the United States registration area, show the mortality rates of these diseases during the period 1913-1915, for the seven States with the highest, and for an equal number of States with the lowest rates of cancer mortality, per 100,000 of population:

A.—States Having Maximum Cancer Mortality Rates.

	1913		1914		1915	
	Cancer.	Typhoid Fever.	Cancer.	Typhoid Fever.	Cancer.	Typhoid Fever.
Average throughout U. S. registration area	78.9	17.9	79.4	15.4	81.1	12.4
Vermont	111.7	7.8	109.9	11.6	104.0	13.0
Maine	107.5	12.0	107.6	16.0	106.6	13.4
New Hampshire	104.4	11.9	100.8	8.7	109.4	7.7
Massachusetts	101.4	7.9	101.2	7.6	104.0	6.7
California	97.6	15.9	97.9	13.4	98.1	9.7
Rhode Island	93.3	8.3	91.2	8.1	92.1	10.1
New York	87.8	10.3	90.0	8.9	92.0	7.6
Average, 7 states	100.3	10.5	99.8	10.6	100.8	9.7
Ratio of cancer to typhoid fever	9.4 to 1		9.4 to 1		10.3 to 1	

B.—States Having Minimum Cancer Mortality Rates.

	1913		1914		1915	
	Cancer.	Typhoid Fever.	Cancer.	Typhoid Fever.	Cancer.	Typhoid Fever.
Washington	53.5	10.3	61.9	10.7	57.2	8.1
Utah	52.1	22.2	45.8	15.9	48.3	9.4
Colorado	50.7	17.0	58.3	17.0	53.4	12.7
Montana	49.4	22.7	51.5	15.3	50.0	12.8
Virginia	48.4	33.3	48.9	27.3	53.7	23.7
Kentucky	48.0	42.7	46.0	41.7	49.7	30.4
North Carolina	47.9	57.4	57.8	56.5	59.5	40.8
Average, 7 states	50.0	29.3	52.8	26.3	53.1	19.7
Ratio of cancer to typhoid fever	1.7 to 1		2.0 to 1		2.6 to 1	

Since from this and the preceding table it is abundantly clear that the mortality of cancer varies inversely with that of typhoid fever in a constant and regular manner, it follows that the causation of these diseases must be governed by some principle common to both; otherwise it is not conceivable that a relation of such character could exist between them. The fact that the relation between them is inverse can only be interpreted as implying that cancer and typhoid fever tend to neutralize each other, or in other words that they are mutually antagonistic. This attitude is of the highest importance for the reason that, as will appear presently, it coincides so perfectly with the relations of protozoal organism to typhoid bacilli in water as to render it certain that these organisms are concerned in the causation of cancer and water-borne typhoid fever.

The relation of cancer to water-borne typhoid fever is obscured in some degree by the inclusion in the mortality rates of cases arising from direct infection, flies, food contamination, etc. If it were possible to eliminate all such cases, the relation of cancer to water-borne typhoid fever would then be seen in its true proportions, and would undoubtedly appear to better advantage.

For the normal development of protozoal organisms and typhoid bacilli in water certain conditions such as temperature, oxygen, food-supply are necessary, but as these are generally present in a degree equally favorable to both these species in all classes of water ordinarily used for human consumption they cannot be regarded as the determining factors of an inverse relation between them, and, therefore, do not require to be considered in connection with this subject. With respect to sunlight, however, the case is entirely different; exposure to sunlight promotes the growth of protozoal organisms but is fatal to typhoid bacilli. Hence in surface waters protozoal organisms are favored, while typhoid bacilli are at a disadvantage, whereas in ground waters the reverse is true; that is, protozoal organisms tend to disappear, while typhoid bacilli are able to multiply freely. The influence of sunlight upon protozoal organisms and typhoid bacilli is of such contrary nature that the relation between them cannot be otherwise than inverse.

In addition to sunlight, another determining factor of this relation must be recognized, namely, the ability of protozoal organisms to feed upon typhoid bacilli and thus to thrive at their expense. It is obvious that in waters otherwise equally suitable for the existence of both species, by virtue of this faculty typhoid bacilli must tend to disappear as the numbers of protozoal organisms increase.

In confirmation of the foregoing, the following passage from Prof. G. C. Whipple's work, "The Microscopy of Drinking Water," is of value: Baisley's Pond, one of the sources of water supply of Brooklyn, is fed by a number of streams which are more or less polluted. During August, 1899, the water of the pond contained a large amount of clathrocystis. Bacteriological examination of the inflowing streams showed that the water contained from 1,000 to 17,000 bacteria per c.c., while the water at the lower end of the pond contained less than 50 per c.c. A study of the analytical records for the same pond during the years 1898-9 showed that the number of bacteria varied inversely with the number of clathrocystis.

"Laboratory experiments made by Strohmeyer and others corroborate the above and show that certain algae tend to reduce the number of bacteria in water. More recent experiments by Emmerich have indicated that certain protozoa exercise a similar purifying effect on surface waters. He has found that two species of the genus Bodo will greatly reduce the number of typhoid fever germs in water. Straining of the organisms shows that the bacteria are absorbed by the animal cell, the action being analogous to that of the white-blood corpuscles in the human body, upon which Metchnikoff's theory of phagocytosis was based. Emmerich considers that these and other protozoa play an important part in the self-purification of streams."

Typhoid bacilli are undoubtedly the primary cause of typhoid fever, and therefore the rates of typhoid fever prevalence must necessarily vary in accordance with any increase or decrease in their numbers. Hence, in addition to the inverse relations already considered, namely, that between cancer and typhoid fever, and that between protozoal organisms and typhoid bacilli, a relation also exists between typhoid bacilli and typhoid fever which is direct or causative, and which, by reason of the fact that it contains a factor, namely, typhoid bacilli, in common with the relation between protozoal organisms and typhoid bacilli, serves to connect protozoal organisms with typhoid fever and also with cancer.

Since it has been shown that the numbers of typhoid bacilli in water vary inversely with the numbers of protozoal organisms present, it follows, in view of the causative relation of typhoid bacilli to typhoid fever, that typhoid fever due to typhoid bacilli in water must also vary inversely in accordance with the numbers of protozoal organisms present in such waters. Large numbers of protozoal organisms, therefore, imply a low rate, and small numbers a high rate, of typhoid fever prevalence.

But it has also been shown that the prevalence of cancer varies inversely with that of typhoid fever; consequently, the influence of protozoal organisms upon the rate of typhoid fever prevalence must necessarily be reflected upon the rate of cancer prevalence in a manner the reverse of that in the case of typhoid fever. Large numbers of protozoal organisms, therefore, imply a low rate of typhoid fever and a high rate of cancer prevalence; small numbers a high rate of typhoid fever and a low rate of cancer prevalence.

Thus cancer is influenced by and therefore related to protozoal organisms; and as revealed by the foregoing, *the character of this relation can only be direct or causative.* Supposing it to be otherwise, that is, inverse, large numbers of protozoal organisms would then imply low rates of cancer prevalence, whereas it has been shown that the contrary is true; further, in such a case the relation between cancer and typhoid fever, which has been established upon the basis of statistical facts, could not exist, for the reason that protozoal organisms would then oppose the prevalence of both typhoid fever and cancer, and would thus obliterate the relation between them.

It appears, therefore, that only one conclusion is consistent with the facts underlying these relations, namely, that the prevalence both of cancer and of typhoid fever is governed by the numbers of protozoal organisms in water. On this basis the reasons which support the view that protozoal organisms are the primary cause of cancer correspond with, and are equally as forcible, as those which apply in the case of typhoid bacilli and typhoid fever.

In concluding this discussion of the causation of cancer it may be said that this article is to be regarded not as a complete presentation, but only as a small sample of a subject so vast as to far exceed the capacity of any single individual. It is believed, however, that the material herein considered is fairly representative of the whole, and that it is sufficient for the purpose in view, namely, to urge the importance of water in the causation of cancer, and to advocate the adoption of measures likely to be effective in the prevention of disease.

Theoretically, the prevention of cancer is chiefly concerned with the elimination of all those factors which are essential in the causation of the disease, but for the practical purpose only two of these —lesions and water—require to be considered. Cancer cannot arise in the absence of a preexisting defect or lesion in the skin or mucous membranes, nor in the absence of living organisms from water, and therefore it follows that in so far as measures calculated for the attainment of these conditions are successful they are at the same time correspondingly effective in the prevention of the disease.

Although precautionary measures against lesions are of undoubted value in certain cases, more especially of the skin and other parts readily accessible, yet, because of the difficulty and uncertainty connected with the diagnosis and treatment of internal lesions, they are inapplicable to all except a small percentage of cases; it is, however, not justifiable on this account to discard them entirely.

The fullest degree of success in the eradication of cancer or any other disease is only to be expected from measures directed against its primary cause. This does not necessarily imply that the primary cause should be isolated. It is sufficient if its nature is known. Nor does it necessarily follow that when the primary cause has been actually demonstrated the prevention of the disease is thereby rendered possible, or even that any substantial progress has been made in this direction; yellow fever and leprosy may be cited as cases in point. Cancer arises from fertilization of a tissue cell by the fertilizing or male elements of protozoal organisms, but when it is realized that more than thirty thousand species of these organisms are already known, and that apparently an unlimited number of other species, as yet unrecognized, exist, any or all of which are to be theoretically regarded as a possible cause of the disease until the contrary is proved; and furthermore, that the processes of fertilization are the most subtle in nature, and consequently the most difficult to investigate, it would appear that the task of isolating the causative agent or agents of cancer is only possible of achievement in an infinite period of time. Moreover, supposing this task were accomplished, there is no reason to believe that measures for the prevention of the disease would then differ in any material respect from those which are now at command.

However numerous or diverse the species of protozoal organisms concerned in the causation of cancer may be, there is one controlling principle sufficiently broad to cover them all, namely, that cancer cannot arise except by contact between a lesion and water containing living organisms. Accordingly, anything which tends to prevent such contact must, in some degree, be effective in controlling the disease; but since nothing can equal the sterilization of water by heat for simplicity, availability, range of applicability, freedom from untoward consequences, and the satisfactory character of the results to be expected, it is unnecessary to consider any other measures at this time.

Protozoal organisms are very sensitive to changes in their environmental conditions, and it is probable that all species are destroyed at temperatures far below the boiling point of water. The effect of even a moderate temperature (115° F.) in controlling cancer has been seen in connection with the incidence of the disease on the skin and breast among the Japanese, and on the basis of that experience it seems justifiable to believe that cancer may be entirely prevented by raising water to temperatures not greatly in excess of those which are customary in Japan. Having regard, however, to the desirability of fixing a standard readily recognized by persons untrained in estimating degrees of temperature, and also to the advantage of destroying at the same time typhoid bacilli and other pathogenic organisms commonly present in water, a temperature less than the boiling point of water is not to be generally recommended.

Sterilization by boiling of all water intended for drinking, washing, bathing, medical uses, or any other purpose requiring contact of water with the skin or mucous membranes, is the only measure really essential in the prevention of cancer. Sea bathing and the application to the body of raw water in any form is to be avoided. Natural ice, or ice not manufactured from sterilized water, is not less dangerous than water of the same class in its liquid form.

413 Broadway.

Autotherapy of Cerebral Wounds.—Mocquot and Moulonguet prepared a vaccine from the pus of cerebral wounds and injected it directly into the patient daily by the subcutaneous route. In three cases thus treated suppuration diminished, the wound improved and the general amelioration was remarkable. The healing was complete.—*Le Progrès Médical.*

PERILS FROM FAULTY POSTURES.

By J. MADISON TAYLOR, A.B., M.D.,

PHILADELPHIA, PA.

PROFESSOR OF APPLIED THERAPEUTICS, TEMPLE UNIVERSITY, MEDICAL DEPARTMENT.

If I were called upon to name one physical fault from which most perils to health arise, that one would be *wrong postures*. This will be more apparent after a survey of relationships of body attitudes to functional competences.

The more graceful a person the more harmonious are the workings of both body and mind, also vigor seems to be thereby longer maintained. This obtains no matter what sort of life was led, excepting of course serious errors of conduct. The crux of the matter is not mere grace of action, the esthetic feature, but the admirable poise, the economies of force in action displayed. Equipoise makes for serenity of body and mind, for equalized expenditures of force in respiration, in circulation, in digestion, hence in rhythmic action throughout the macrocosm. Not only so, but the affective faculties, volition, emotion, the primal urgings of fear and anger, equally demand equilibration.

That man or woman who habitually and instinctively performs all acts with economic energizing from impulse to execution, loses the least motion, wastes the smallest amounts of force by the way, and possesses a superiority over those who are awkward, careless, or spasmodic. Such beings move through life with ease; with the least friction; little is left to chance, to accident, because they adjust themselves intuitively to external forces and circumstances. They automatically save themselves from perils innumerable though rarely conscious of their escape.

The subject of *posture* is thus cited to serve as a warning against sacrificing balance, and to encourage efforts at acquiring equipoise in both repose and in action. The prime condition is to achieve normality of body adjustments as an automatism, a habitude.

Let me sketch in shortest space why and how faulty postures are capable of acting harmfully on the whole organism:

Obviously that mechanism best serves its purpose whose component parts work in harmonious economic interaction. Any departures from ideal adjustments must necessarily cause losses of motion interfering less or more, with whatever function the part or group or system was designed to serve. Ideal results of voluntary movement fall short in two essential particulars: (a) Unless the objects or aims or purposes which the mechanism is calculated to discharge are fully met and discharged; and, (b) unless the make up, structure, composition, therefore integrity of structures are freed from danger of suffering harm by undue friction, attrition, strain and waste motion to which faulty adjustment renders them liable; and, (c) unless movements voluntary and also involuntary or automatic are so well controlled as to reduce to a minimum the perils of awkwardness, chance collisions, slips, bumps, falls, or inefficiency.

The body and mind being one unity, a self-guiding, self-adjusting sentient mechanism, therefore perfection of action, interaction, and reaction can be expected to be and remain only while certain ideal postures are maintained or economic attitudes assumed.

Individuals vary so widely in both domains, *i.e.* the self-guiding and the developmental, that, as a matter of fact, faulty attitude habits, both static and mobile (*i.e.* while maintaining attitudes and during work), leave much to be desired of the ideal; hence fail of ideal motor economies, hence of the highest output of purposeful effort—or proficient energizing.

Thus it should be plain that faulty habits in attitude, the positions one voluntarily assumes (posture being that correlation of parts unconsciously assumed), lead to almost endless perils through disadvantageous mechanics or confused function.

Disadvantages of posture influence: (1) While at work, performance of any sort; (2) while at large, moving about to and from destination, amid thoroughfares occupied by moving vehicles or while traversing by-ways out of the common where the element of poise, balance, ascending or descending declivities, etc., call for some care in locomotion.

Another obvious fact or significant principle is that every one, young or old, deserves, indeed, really needs training in attitudes. An excellent example of the value of conscious control of subconscious acts (the return force of faulty habitudes) is given by F. Matthias Alexander in his book, "Man's Supreme Inheritance." He cites the attitudes of Dorando winning the World's Marathon (1) while he was moving along at his best, showing all the superb effects of conformation and right training. Contrasted with this is (2) Dorando's attitude toward the end of his heart-breaking race, desperately wearied, and, whatever conscious control of his muscular mechanisms he may have possessed, he was at the moment completely under domination of subconscious (or subjective) control; out of communication with his reason.

Small doubt can linger in the minds of any who will look critically into the daily evidence that a large variety of disabilities, disorders and some diseases can be not only prevented, relieved, but oftentimes cured by education (and re-education) in conscious control. This includes accurate training in suitable attitudes. Space forbids dwelling on details of causation and progress of specific conditions. We must leave elaborations for another time and now merely commend the importance of the principle sketched out.

Concrete illustrations appear on every side of pathetic limitation of usefulness by neglect of recognition and observance of precautions in conscious control of attitude.

Closely allied with posture is the whole subject of behavior, poise between impulse and restraint, emotion and motion, expansion and concentration. Man's supreme inheritance is the product of his power for poise, for self-balancing the push and the pull, "of equanamitas," his "cosmic urge," elan vital, and his capacity to limit his streams of energizing, and to confine them into natural or rather controlled channels. Impulse and its mastery is the loftiest achievement.

That is a small part of man's best inheritance which has provided him with mere mechanisms; miracles of complexity and adaptability and utility

as they are. None the less the whole of earned success, of achievement, rests on how he exhibits and exercises conscious control of those mechanisms.

Right postures and attitudes depend for their integrity upon the integration of neuromuscular mechanisms. These stand so high in his hierarchy as to be on a par with, indeed, they are essential parts of, his cerebrospinal, his reasoning mechanisms.

The component parts are balanced muscles; their harmonious energizings from sensory impressions on the brain centers to the uttermost confines of the periphery. Here we reckon with the special sense kinesthesis.

Likewise and indissolubly implicated with these are the reflexes; accommodations between sensations of motor origin and central receptive mechanisms, *e.g.* the otic labyrinth, the cerebellum, the centers for sight and the muscles of the eye along the whole group of sensory and sensori motor coordinating centers and structures.

Body equilibrium is governed by the vestibular apparatus of the internal ear through which the muscles of the skeleton receive impulses enabling them to maintain body balance.

The correlate of kinesthesis is akinesis—rest, sleep, the great conservator of energies. And this depends upon balanced nutrition, poised metabolism. The whole are regulated by the ductless glands.

Let us mention a few of the manifold departments of functioning in which body defenses can be economized, conserved and fortified by conscious control of attitude. Note that by so doing serious perils are oftentimes escaped, wholly or in part.

In a second paper will be presented a summary of illustrative citations from literature showing specific applications of adapted attitude as a direct or indirect means of rendering service. Among the vital systems or functions capable of being conspicuously aided by control of attitudes are:

Reproduction.—Economic attitudes during gestation are of peculiar importance to the welfare of mother and fœtus. Normal postures of the static mechanisms, the development of the bones, ligaments and limbs, and especially normal development of the muscles concerned in retaining right posture, are of paramount significance in the complex processes of nutrition of both. On adequate support of the abdominal parietes depends holding up the increasing weight of the unborn child.

During parturition it has been demonstrated to be far safer and more economical to assume the attitude of stooping on the ground (squatting) and holding onto a fixed support, thus enabling the pelvic muscles and outlets to work to advantage, and the compressor action of the associated muscles to do their duty in accord with conformation. The customary atttiude of lying on a bed places all these structures at disadvantage. In consequence labor is delayed, presentation is readily disturbed, and the perineum is too often ruptured.

Respiration.—All the acts concerned in tissue respiration depend on normality in postures. Respiration consists of a group of automatic procedures which are, however, capable of volitional control and deserve to be trained. Unless some advice be supplied the tendency is to acquire faulty habits of stooping. Hence undue compression is exerted on the lungs, heart, and great vessels, whereby oxygenation is limited, impaired. Guidance is necessary during youth and should not be omitted in later life, especially by those who show anomalies in breathing.

Circulation.—The whole group of organs, the heart, bloodvessels, and kidneys are peculiarly susceptible to impairment from faulty postures. They are also closely correlated with both respiration and digestion.

Failure of right cardiac action leads to so large a group of disorders that correction of myocardial anomalies oftentimes is the key to recovery, repair, efficiency, and health. During any form of exhausting illness, primary attention must be given to conservation of the heart. The only rest this master organ gets is the pause between systole and diastole. Whatever interferes with the rest period directly impairs integrity of the entire vital processes.

During infections the heart muscle is gravely taxed, often seriously disordered; it demands fullest rest, and for this right posture is paramount. The attitude of lying down is best. Many other factors enter. Reversal of attitude aids in resting the over-burdened, over-weakened myocardium. Hence devices such as raising the feet of the bed; of insistence on absence of exertion; of elevating the legs during convalescence, all contribute to aid recovery of the organism as a whole.

Even during health, when exhausted from any cause the most prompt circulatory equilibrium is assured by conservative attitudes. After long marching soldiers will recover tone most quickly by lying down and raising the legs. Emptying of the veins is thus aided, stagnation in the abdominal viscera is relieved. The feet become restored to their best competence. That distressing and disabling condition, chronic leg ulcer, can be prevented by emptying over distended veins by attitude.

Shock of all forms and degrees involves secondary hypotension and next to warmth, quiet, rest, is dependency of the head and raising of the legs an essential to recovery.

Digestion and Elimination.—All the hollow viscera, tubes, and their supports act at best advantage while normal attitudes are preserved. Man, the only upright mamal, has not yet wholly become adjusted to radical changes from his original conformation. Hence the normal postures, the interrelationships of those organs need to be sedulously conserved. Adequate power must reside in the abdominal parietes and associated structures.

Defecation in particular depends largely upon the attitude assumed during the act. This is the primal biological one of stooping, squatting down, like the savage to-day; thighs pressed close against the abdomen; the arms encircling the knees, and the whole compressor group acting together to advantage. The danger of inducing hernia is thus greatly reduced.

Sophistication, laziness, whimsical customs have much to answer for in causing disorder, disease, and premature death. The significance of attitude in defecation is vastly greater than it is possible to impress upon the consciousness of custom-ridden constipated humans.

Interrelationships of the abdominal viscera

(enteroptosia) are so frequently disturbed as to be almost the rule—Albu says at least one among five men and three in five women. While this does not always seem to cause distress, it is a disurbance and must be reckoned with as a background of much disorder and deserves correction.

Then there are the recently discovered intestinal adhesions, kinks, angulations and the like, secondary factors in visceral stasis. To be sure, these are due to diseased states, but how much original defect may be caused cannot be stated. It deserves closer study.

Special Senses.—Attitude is a large factor in conserving or in destroying acuity of vision. It may have less to do with hearing or feeling or smelling, but the principle is equally important. Upon the eye falls the major fatigues, exhaustions, hence varied and widely associated disorders, nerve strains (see Geo. M. Gould's findings as to "Effects of Visual Function on Health").

How far faulty original attitudes influence visual development and conservation can not be demonstrated, but can not be ignored. Certain it is that vision, long fixed and concentrated, the relationships of light, of nearness or distance of object viewed, along with attitude of head, of neck, of chest, back, etc., must have far more to do with original development than even to disorders of those of middle or advanced age.

Genitourinary Apparatus.—Volumes have been written, hours of discussion squandered, on the subject of maladjustments of the female organs of generation. It is fair to assume a large part of these could have been prevented by primary conservation of attitudes and hence of visceral interrelationships.

When shall we learn to conserve man power at the source? Certain it is, in my opinion, much can be achieved by training in attitudes to prevent and relieve prostatism. Long hours of sedentary work must influence evilly the entire associated soft structures which can only be and remain sound through normal motor use of correlated structures. Beginning and well advanced prostatism can be greatly retarded and relieved by ample exercises designed to restore normal posture. (See article, *Journal of Urology and Dermatology*, 1917.)

Locomotion.—It will be obvious that nicety in adjustment of the static and gross muscular mechanisms must exert significant effects on economic locomotion. The key to posture is the attitude of the pelvis first, thorax second, the head and neck third. I can only allude to locomotion in its relationship to attiude here, having elaborated the subject elsewhere.

One point I must mention: The leg is equipped with both flexor and extensor muscles. Unless these are both used and to an equal degree, alternately, the act of walking can be only partial, inadequate, and inefficient. As the leg is thrust forward the extensors are used; as it is drawn back the flexors come into play or should come—when passing the mid line. This flexor action should be equally forceful with extensions. A right attitude of the pelvis makes this possible.

One word as to that pediment of "the human understanding," the foot. The foot is at the mercy of fashion in shoes. Most of these distort the relationships of parts and in consequence unnumbered miseries ensue. Permit these parts to assume habitually normal postures and avoid the forced attitude of ill-fitting foot gear and locomotion becomes and remains a pleasure as well as a source of profit.

Finally, give nature a fair chance to work unhindered by noninterference with normal postures and supply early and late intelligent training in economic attitudes, and human miseries, disorders, and decrepitudes, it is fair to asssume, will be reduced much more than fifty per cent.

1504 Pine Street.

RESISTANCE AND TRANSFERENCE IN PSYCHOANALYSIS.

By C. P. OBERNDORF, M.D.,

NEW YORK.

CLINICAL INSTRUCTOR IN NEUROLOGY, CORNELL MEDICAL SCHOOL.

It is well appreciated by any physician with experience in psychoanalysis that the difficulties encountered in analysis depend not only on the intricate character of dreams, but especially upon the resistance which the patient develops, both consciously and unconsciously, to the revelation, dismemberment, and interpretation of painful thought associations which have been voluntarily or involuntarily kept carefully guarded. Inasmuch as the "likes" and dislikes of all patients for their physicians, and inasmuch as the apparently intangible determination of reaction of one individual to another's personality, have fundamentally the same unconscious basic sources (which we shall here designate "transference" and "resistance"), the topic may be of interest to those not directly concerned with the technicalities of psychoanalysis.

The essence of the procedure of psychoanalysis, delving as it does into the individual's intimacies of the past, usually a vexatious and torturing past, invites a conscious resistance which is comprehensible to all. One of the commonest mental tendencies is to allow the recollection of unpleasant events to slip into the background, so that in reverting to childhood days we are apt to regard them as singularly happy, notwithstanding their many concomitant poignant troubles and disappointments.

Most persons naturally choose the most agreeable way offered for the solution of any difficulty, and psychoanalysis cannot be represented to the patient as a remedy of unmixed pleasure. Compared with the proposition of a trip to California or a six weeks' cure at a spa with a companion or nurse, it has little to attract the self-pampered neurotic. A mere statement of the laboriousness of analytic procedures may arouse sufficient conscious disapprobation to prevent further acquiescence on the part of a patient, so that treatment is never begun. However, where it is undertaken, before long active resistance is almost invariably raised on one ground or another.

Patients may consent to psychoanalysis with such misgiving or with such eagerness as to arouse suspicion on the part of the physician, for either may be construed as an evidence of unconscious resistance. The first indicates distrust of the physician to ameliorate the symptoms; the

second, a desire quickly to unburden what the patient considers to be his share toward the analysis, and, having done this, without appreciable benefit to his condition, to prove the method a failure so far as he is concerned. "I've told you all there is to tell" is a frequent though untrustworthy protest from patients. In reality this type of denial is a defense against further investigation which has its roots firmly imbedded in the unconscious. In cases of this latter class, the handling of the resistance becomes the main factor from the first visit. The failure of the analysis, in turn, would permit the patient to retain his illness—a thing which many patients, in spite of their protestations to the contrary, unconsciously desire.

A patient who some five years ago was, with unsatisfactory results, analyzed for insomnia and inexplicable moods of depression, and whose analysis was at the time interrupted by external circumstances, recently returned to resume the analysis. While I was attempting to determine the origin of the flippancy with which she persisted in confronting me from time to time during the second period of analysis, she suddenly became quiet. On urging, she acknowledged that I had been correct in maintaining that her flippancy constituted a protection against analysis. She added, however, that the flippancy was merely a new method of defense, substituted for that of conveying wrong impressions, which she had consciously done during her first series of visits, to baffle me. Furthermore, notwithstanding that she had prevailed upon herself to resume analysis, even on this second occasion she had lied where it suited her purposes in order to supplement the effect of the flippancy.

This clinging to an illness becomes comprehensible when it is understood that a neurosis often forms a compromise between an unconscious wish and a repression. The sickness constitutes the patient's own solution of his perplexing problems, and may be construed as an effort to "eat his cake and keep it." Unconsciously he desires to cling to the compromise in the form of existence that the neurosis represents. Thus patients, after their resistance has been overcome, have often acknowledged that they consciously fought stubbornly because they appreciated that if a cure of their neurosis were accomplished, it might bring them face to face with realities, which at the time appeared more distressing to them than their pathological symptoms. In fact, one patient who entered treatment for homosexuality, feeling that he was on the way to a cure, calmly informed me that he had decided to continue in his homosexual state rather than endure the loss of old associations, which he felt he must do if he became heterosexual—in other words, the state which would result from the cure seemed more disagreeable than the disease.

Thus a paramount task of the analyst resolves itself into the handling of these resistances as they arise. This is accomplished, or rather accomplishes itself, in permitting the patient first to transfer his loves and longings, hates and jealousies, upon the physician himself. All persons harbor, to a greater or lesser degree, floating affects which are seeking fixation on some object. In neurotics, no matter what symptoms may be presented in their malady, this is especially the case.

Neurotics suffer from an incomplete utilization of their affective energy, which remains entangled and bound about their various symptoms. Where such affects, especially old and forgotten affects of childhood, are released during the course of an analysis and come to the surface of consciousness, they are displaced upon persons with whom the patient is most intimately in contact at the time. The analyzing physician is at the time of the analysis the most convenient, and as a matter of fact, if he be understanding, the safest object upon which to unload this mass of affects.

Transference, then, is a temporary regression to infantile affects, with an adaptation of them to the immmediate real situation. It is evident, therefore, that transference is paramountly a subjective process with the patient, during which he invests the physician with the character or characteristics of his unconscious antipathies, his ideals, or his yearnings which he desires to see realized. How purely reflective the process of transference is may be judged by the fact that it is the experience of any analyst to appeal to different patients in a great diversity of characters on shallow grounds. Thus I have been considered in turn by various patients to be a serious student, because of a high forehead; a homosexual, because of neat dress and wearing a clean straw sailor hat; a sport, because of wearing a red tie; a priest, because of solemn countenance; effeminate, because of a sweet smile; masculine, because my office smells of tobacco smoke, etc.

A more or less potent transference is the rule at the outset of all analyses where the patient actually begins treatment. One of the most accurate indications of the degree of transference is the punctuality with which the patient keeps his appointments. When the transference is positive, but not necessarily excessive, appointments are kept almost to the minute, so that when the patient is late, allowing for unavoidable delays beyond his control, the physician may confidently regard it as an evidence of resistance which he should not neglect to attempt to unravel.

At times transference is shown in presents given the physician by the patient. It has been my experience that when I handled transference poorly, I was apt to be rewarded by some token of esteem, for which I paid later in a stubborn resistance which might terminate in discontinuance of the treatment. It may be considered a fault in technique if transference is permitted to proceed to the gift-giving point. Excessive transference can be regarded only in the light of a danger signal, which, if unchecked, will militate against a permanent cure and certainly prolong the treatment.

During the course of analysis, symptoms of resistance of varying intensity (which is then in reality a negative transference), appear, and form the most exacting technical aspect of psychoanalysis. Resistance in this sense is always based on unconscious motives, and usually is dependent on infantile impressions.

Resistance may be further distinguished as resistance on the part of the patient to acceptance of views, which he unconsciously harbors but which conflict with those which he consciously fosters, or on the part of the analyst himself to an impartial

consideration of all aspects of the problems presented. Closely associated with the patient's own resistance, but really a factor quite apart, may be the opposition advanced by the patient's family to the treatment. At times this opposition becomes a cardinal influence, in that it supports and protracts preexistent resistances developed independently by the patient himself as a result of the bringing to consciousness ideas which he is accustomed to disfavor consciously.

The conscious initial rationalized resistances can usually be overcome. Objection is met by fact. Most persons who seek analysis have usually at their own initiative or at the direction of physicians, essayed the gamut of water, rest, and electrical cures, all prolonged and expensive methods. Nevertheless, resistance may be disguised as an apparently well founded objection to the length of time, the tedium, or the expense of the procedure. These can all be plainly answered, and, if the patient still finds objections, it seems to me to be far better to allow the proposed treatment to rest in abeyance.

Early resistance to revelation of unsavory experiences usually vanishes after analysis has been in active process and the patient appreciates that these occurrences are regarded by the physician in the light of dry, impersonal facts, which arouse neither censure nor sympathy. Most active, and perhaps most logically defended, is the objection to the analytic interpretation of certain manifestations. Eventually this disappears, but it may frequently be obviated if interpretation of the material gleaned is deferred until the patient has become well familiarized with the general tenets of analysis. Not infrequently in the course of conversation the patient himself offers an interpretation of a casual extraneous experience which corresponds to the light wherein some of his own more important complexes may be viewed. I am inclined at that time to emphasize especially his own interpretations of extraneous reactions as a means of lessening resistance to subsequent analogous explanations of his own symptoms.

Opposition on the part of the family, when present, forms the most stubborn and potent of all forms of antagonism, as its source usually lies beyond the immediate range of the physician, operates clandestinely, and particularly reinforces early trends upon which the unconscious subjective resistance of the patient is founded. The family usually remains ignorant of the aims of analysis and cannot be enlightened by the gradual introduction of the subject through which the patient becomes reconciled to it. They not infrequently infer that the neurotic, whom they often suspect of consciously imposing on their leniency, is further pampering himself by engaging in sympathetic little chats with the physician. Seeing little improvement manifest in the patient, as is so often the case at the outset of analysis, they advance objections on the score of further expense, which has usually been considerable before analytic treatment is begun.

The most serious obstacle encountered from family sources is met when a complementary attachment of the patient to a neurotic relative, which the patient may himself have regarded as rather unnatural and have been unconsciously attempting to break, is finally ruptured under analysis. Such a relative, confronted with the loss of something which has been a distinct source of pleasure, may instigate an active campaign, openly or indirectly, to interrupt the procedure which is so manifestly responsible for the alteration in the patient's affections. Such a person would prefer to have a son or wife sick, than apparently to lose them. Naturally enough such a relative, whose own attitude continues unaltered, cannot be brought to appreciate that unhealthy attachments can never, in the end, continue to be happy or entirely satisfactory. One could not expect a widowed mother, who had crawled into the bed of her thirty-year-old daughter every morning to be fondled by her, to relinquish the habit without a murmur when the daughter's reciprocal attitude changed under analysis. In fact, the mother's protest increased in intensity until it became a veritable clamor against the physician. This added immeasurably to the resistance which had developed independently in the patient as the result of the transference upon the physician of the interest formerly exhibited to the mother and which the patient realized must inevitably remain unrequited.

On the whole, it has seemed to me preferable, where possible, not to become acquainted with members of the patient's family. Even at the initial conference it seems advisable to explain the requirements of analytic treatment to the patient and to allow him to make necessary arrangements with the persons upon whom he is dependent. Interviews lead to distortion or misinterpretations of the physician's aims in the discussion which invariably ensues at home after the visit of a relative, and this is avoided if the affair be restricted to the patient and the physician.

The resistance of the physician himself to the correct or unbiased interpretation of the material which he has presented to him by the patient is quite apt to be overlooked by him. The physician, no less than the patient, is not immune from having his own vision somewhat obscured by personal equations. He may fail to recognize certain qualities in the psyche of his patient because he is antagonistic to admitting these qualities in himself. On the other hand, he may be vaguely conscious of the existence in his own make-up of the characteristics which he sees in his patient, and therefore be unconsciously inclined to condone them. The patient need not be extraordinarily keen to sense this sympathy, and while he may relish it, will seldom adjust himself through it.

Largely on these grounds has the dictum gone forth from the Zurich School, that an analysis of the psychoanalyst should be part of his technical equipment. Some years ago du Bois of Berne virtually admitted that his persuasive method was almost entirely dependent upon his personality, *i.e.* it depended upon the transference of the patient upon him, an elderly, full bearded, sympathetic, understanding man—in analytic terms, the ideal father, who prevails upon the patient to follow his counsel. Du Bois remarked, "Only a good man can use persuasion successfully." As illustrative of the fundamental difference between the persuasive and analytic methods, one might readily paraphrase his

dictum into, "Only an unbiased man can use psychoanalysis successfully."

Resistance of the patient may exhibit itself in diversified and apparently completely antithetical ways. It may take a form best classified as purely personal antagonism to the physician, rationalized on one ground or another, or resistance to the method which he employs. At times this may be displaced either way; *i.e.* the physician may receive the blame for the method, which is distasteful to the patient, or the method may be blamed for the patient's purely individualistic dislike for the physician.

The following incident is recorded as a typical example of a transference turned into a rationalized resistance, which, however, was analyzed with the result that the further analysis of the neurosis could proceed normally. The patient, who had been under analysis for four months and was coming three times a week, one morning sent me this letter:

Dear Doctor: I have decided that I will come twice a week after this, so that I can go back to your first suggestion to pay $10 a month toward my bill. It will make A.'s (a brother) contribution to my bill less. I think it will help me a little toward that freedom I want, and besides I will have more toward my incidentals. I will also have more time for swimming and getting back to my friends. I think a sex outlet can be had in work and athletics as well as in sex intercourse, social and otherwise.

I feel I have been floundering terribly lately, my headaches have increased. I think it is a mistake to look for more psychology, as I intended to do at those Labor Temple lectures. I believe I am getting all I can make use of at present—enough for my needs and at the rate I can go. I have been trying to put myself on a level with you—trying to reach your plane of education—not only you but others I meet—college girls, etc.

It was better for me to follow someone else's advice. I suppose in the long run I would be better off if I followed my own—I mean in the long run that I have to know what I really want. But at present I don't. I came in to-day thinking that I would keep up my swimming and my thoughts were divided with the psychology at Labor Temple. I thought this would be a good way of dividing my attention from you:....."

While the contradictions in the rationalization of the wish to come only twice a week because of, or notwithstanding, the "increased headaches and floundering terribly lately" are apparent, in the main the contentions advanced by the patient are that three times a week occupy too much time to the exclusion of other pursuits; that it would allow her more money for the enjoyment of pleasures if she came less often; and that the amount of psychology which might be crammed into two hours a week would be all she could grasp. Significantly she adds that she had considered the other outlets as a means of "dividing my attention from you."

In explanation of the circumstances it may be stated that the patient had been put under my care some four months before the letter was written. Three years before that time she had had a violent love affair with a man who was her inferior in position, morals, and manners. After she had ruptured this alliance, so unsuited to certain sides of her character, she suffered from a severe emotional disorder and had since then been under the care of various physicians continuously, both outside and in sanatoria. When the love affair was broken, her freed love energy had attached itself to one physician after another and in turn had descended upon me.

It is impossible to record here the numerous factors which originally caused the schism in her emotional stability. It must suffice that an almost hopeless disintegration existed, and I became invested in her eyes with many spiritual, ethical, and social qualities which corresponded to her earlier ideals.

Some of her earliest childhood affects found egress, as betrayed by her remark, "When you were stern with me, you were like my father—I liked you better then." It may be remarked in passing that it was the impression of the patient that the father had attempted an assault when she was about five. In any case, he had beaten her until she bled, when, as a child, she had related to him that an Italian had offered her money (presumably to induce her to permit a sexual aggression).

She had long struggled to bridge the gap between a strongly inherent sensuality, which she considered sordid, and fanciful aspirations for refinement and cultural achievements, which it had never been her fortune even partially to realize.

Just as she had, in her desperation at the futility of ever approaching the plane of her idealism, plunged headlong into her unpropitious alliance with an uncouth individual, so now, recoiling, she swung to the other extreme, that of her idealist love fancies, with which she found it possible to invest me. At times this idealism was adulterated by frankly sexual thoughts. While fully aware that any consummation of her fancy was impossible, it remained to her a pleasantly treasured illusion. This intense transference became very apparent early in the analysis and had been explained to her, with fair appreciation on her part, and the analysis had proceeded quite smoothly. But an ideal of this type, fulfilling so urgent a need and enveloping a convenient object, is not easily dispelled.

When the time came that I had planned to take my vacation (four months after the patient began treatment), I simply informed her of my intention, believing that she had sufficient grasp upon her neurosis for me to interrupt treatment temporarily.

Upon my return I noticed a decided resistance, but allowed it to pass, and shortly afterward received the letter quoted above. When motives instigating the letter were sought, the investigation revealed the following situation: When I departed upon my vacation the patient felt that I had not shown the proper consideration for her and had resented it, but had said nothing of it. Shortly after my return I had made an appointment with her for one o'clock, which she kept promptly, foregoing her luncheon in order to be punctual. I, however, having been delayed during my morning work and, being at lunch at one o'clock, finished my meal, which made me about fifteen minutes late. I excused myself for my tardiness. She surmised that I had been at luncheon and inferred that I was not showing as great a personal interest in her as she had in me. She had tried to "put herself on a level with me" and I had rejected it. Thereupon she sought means of revenging herself upon me. By decreasing the number of visits she would make me feel her absence and at the same time humble me by disregarding my opinion as to the number of visits I thought desirable; *i.e.* put herself not on a level with me, but above me.

According to her rationalization, the motives for diminishing the number of visits were material. Back of it, however, rested a powerful transference which had not been completely dissolved and turned into personal resistance. This interpretation is reinforced by a letter which I received on the day following the visit when the first letter was discussed.

"When you made up your bill for the month (August) that you were away—I counted that you would charge me $30. Your bill was $35. I reckoned that you should have suffered matrimonially (this is a slip of the pen as patient meant to state monetarily) for having stayed away. It bothered me a whole lot. I have always been, nearly always been exact, not only with regard to money but time also. I spent time figuring out each visit. I couldn't come to any conclusion. It bothered me the next day. I thought you charged me more because I wouldn't have such a "hold" on your affections—that was the best way to kill some of it. I began to find fault with you. But I saw at last that I was small, and that it was up to you to make your bill as you chose and that you couldn't have done any differently—any better. This past month, when I stayed home, I did not expect you to deduct from my bill. I wanted you to charge me the whole bill because then that would have made up for my nasty attitude, but anyway I thought you were very fine when you did it."

It is evident that the transference was not yet entirely broken—I am still "very fine" in my actions. As a matter of fact, it continued a serious problem throughout the arduous case. Nevertheless, some of the aura with which the patient had surrounded her ideal had been removed—with the result that the patient no longer struggled so acutely between her conflicting personal reactions of loyalty and revenge. It is needless to add that none of the patient's rationalizations were retained when the true source of their inception was brought to her attention.

While such transference is an absolutely essential and really unavoidable part of the technique during the initial stages in order to secure any degree of co-operation, it subsequently lapses without detriment to the patient.

Transference alone may serve to alleviate many symptoms of which a patient complains, but the result is usually transient as it is dependent upon the persistence of the transference. In such cases the effect is attributable to a substitution or a sublimation. At times, although such a transference in the physician wanes, the patient, having in the meantime acquired a better grasp of his problems, is quite capable of directing love energy into other sublimative and productive channels. Freud recently remarked, with his characteristic penetration, "The treatment is worthy the name of psychoanalysis only when the force of the transference has been utilized to the subjugation of resistance, for only then does a recurrence of the sickness become an impossibility, even after the transference has been destroyed, as of course it should be."

249 West Seventy-fourth Street.

Anicteric Spirochetosis.—Favre and Mathieu refer by this term to the rare cases in which the parasitic cause of Weil's disease is found in the urine in association with atypical general symptoms, among which icterus does not figure. There is a failure of the health and forces, and a suggestion of atypical malaria, without initial chill or true intermittence.—*La Presse Médicale.*

WHY IODINE? WHAT IODINE?

By Douglas H. Stewart, M.D.,

New York.

There are many able physicians who will neither abandon the use of iodine nor will they adopt the use of any chlorine product whatsoever, when it comes to a question of the proper treatment of wounds. It must surely be evident that such conduct has at least one good supporting reason, in the axiomatic fact that chlorine will attack and destroy sutures. Years before the existence of the present fad for acidulated chlorine compounds the writer did suggest the value and use of calx chlorinmata dissolved in diluted acetic acid; but he has endeavored always to assert very clearly that chlorine was destructive to any suture or ligature; no matter whether of fabric, of tissue, or of metal. As for silver and other wires, those were found to be converted into chlorides of the corresponding bases. Even now at this late day nothing has demonstrated the occurrence of any alteration in the workings of fundamental chemical laws, so let us take for granted that chlorine will attack sutures; either within a wound or elsewhere, if moisture be present.

When a deep and sutured wound is thoroughly and profusely irrigated with chlorine, then the scar of that wound may confidently be awaited as one that will require repair, in months or years after an apparent healing. This is so, because of the existence of intravulnerary spaces and these together with a subsequent yielding of the cicatrix to intravulnerary pressure would be rather reasonable certainties; after catgut stitches under tension had been submitted to contact with a chlorine solution. If the reader will but select a test tube, will fill that with anyone of the popular chlorine antiseptic solutions, preferably one suggested by a detail man, and if he will allow a few strands of catgut to lie in that solution for a short time; then or after his consideration of the destruction there evidenced, even the boldest and most reckless experimentist would hardly defend the act of putting any such solution upon or within any sutured wound.

Apparently it is thought in certain quarters that manufacturers are very much to blame for advising the employment of their chlorine preparations for wound dressing purposes; but the present writer does not take that view of the subject at all. So far as his knowledge goes manufacturers, advertisers, detail men, etc., have been scrupulously honest and have insisted upon the fact that their chlorine product would destroy dead tissue in a wound. If a catgut stitch that runs from wall to wall of a wound is not an excellent example and specimen of a thoroughly dead and altogether tissue-like material; then will some learned pathologist or biologist please tell us what this "common but unobserved" thing called catgut really is; for many of us have taken for granted that a catgut suture properly placed is "dead tissue within a wound," and as such chlorine will surely attack it.

At any rate, the present writer is using chlorine only upon a wound or within a wound of such a nature that it may be closed by the ancient in-

carnating bandage or by acupressure; so that rotting of fabric or the presence of tissue ligature destruction is not a factor that is worth consideration. Surely it is not necessary to pursue this matter further because the reader may make any simple test-tube experiment that is satisfactory to himself and may tell about his result as he finds it. One thing he will readily discover and that is why some men cling so closely to iodine that they will not give chlorine a patient hearing, if its merits are spoken about in their presence.

The author has tried many iodine preparations and has at least a half dozen of such that he finds a use for at times. It will suffice to mention three of them in this place together with an advantage in the use of each form.

Bottle number one contains alcohol to which crystals of iodine, in excess, have been added. The supernatant liquid when unshaken is the 10 per cent. tincture of iodine that is so often mentioned in the literature of surgery. It is an ideal and powerful counterirritant, which statement will enable one to determine whether he desires to employ its germicidal power upon a wound or unbroken surface, or whether he does not so desire.

Bottle number two contains iodine hydrate (4 per cent.). Its efficiency in arresting pimples, furuncles, and carbuncles is so prompt and good that it reigns almost, if not quite, unrivaled in its capital antagonism to infection with the staphylococcus. As an antiseptic preliminary to puncture of the skin for hypodermic or intravenous medication it has had ample trial and much approval. After application it fades quickly with nothing like the stain or the dermatitis of an ordinary (7 per cent.) tincture. Used in wounds it gives a short and sharp snip that is not comparable with that from the tincture of iodine U. S. P.

The third bottle contains the vinegar of iodotannic acid (acetum acidi iodotannici). Its formula is one ounce of U. S. P. tincture of iodine rubbed up with a drachm of tannic acid and with three additional ounces of dilute acetic acid. Should there be any deficiency the whole mixture is finally made up to four ounces, through the addition of the acid. Within the test tube, in the Petri dish, or upon a slide it may be estimated as about equal to 1-2000 or 1-2500 mercury bichloride in water. But upon a wound or upon an infected area of the living human body under work-a-day conditions its superiority is so great that a comparison is impossible. For that superiority is apparent from every angle and point of view. As to its effect upon catgut it hardens that and tends to preservation rather than destruction. Whether it will convert a wound from wet to dry in a very short time is largely a matter of complete contact.

Take it all in all for general office use it is one of the most satisfactory of the preparations of iodine, and lends itself readily to almost every conceivable purpose for which iodine is employed in throat, vagina or urethra, though it does come short as a counterirritant.

The present writer's experiments must have many hidden witnesses, because every little while a letter arrives from some previously unknown source, which letter informs the aforesaid writer about what he is doing. This has a value in calling one's attention to points that might otherwise go unmentioned. It is suggested that something be said about compound fractures, about osteomyelitis, and about other matters, because as one letter states, "Even the nurses know the difference." Perhaps this is as good a place as any to state that iodine and chlorine are out of place under an airtight splint. Through a fenestra in a splint tannin solution No. 119 may be put upon and into a wound *ad lib.* Pads may be used as covers for that wound and through their gauze substance purple may be run or soaked. Where the tannin and purple come in contact iodotannic acid will be formed. In short, the wound will be tanned and the bandage will be iodized. The formula for paraffin purple is to rub up with a little ether, iodine and potassium iodide āā gr. xl, calomel gr. xii, and add slowly liquid paraffin ʒiii. A mortar and pestle are essentials. This purple runs through and into gauze by a visible capillarity. A little care with a little patience in application will fulfil every requirement.

This expedient has been tried with approval in burns, cellulitis, dermatitis, and similar conditions. It may be as well to add, even though it is hardly necessary, that neither tannin solution nor purple will attack rubber or any suture material; and if the application of either preparation or of both together gives rise to pain, or the complaint of pain, then some very unusual condition must be present. Whereas such statements as "We have used quarts of it here," and "This hospital has a bottle on every floor," would rather tend to show that purple and tannin, either or both, were giving some degree of satisfaction in services where everything (and anything) else in the way of application is available and comparable.

128 West 86th Street.

THE TERROR THAT COMES IN THE NIGHT.

By EDWIN F. BOWERS, M.D.,
NEW YORK.

The wisest man that ever lived once said "He jests at scars who never felt a wound." In similar fashion we make light of the terror that comes in the dark to those more delicately organized and more susceptible to external and internal impressions than we are.

And yet, perhaps, we ourselves may be entitled to little or no credit for our freedom from nightmares and frights, or for our fearlessness in the creaky, whispering dark.

The credit, if due at all, should go in large measure to certain steady-nerved, strong-willed ancestors who bequeathed us a nervous system and a set of racial memories that fortify us against fright under conditions where others might melt with terror.

Indeed, it is now conceded that the most serious and stubborn affections that nerve specialists are called upon to treat are those caused by the fears and frights of ancestors. Not immediate ancestors —although these are responsible in various ways

for considerable of our nervous instability—but of our monkey-like progenitors, our great-grandfathers, ten thousand times removed, back in the flying-lizard, giant fern period. This may seem difficult to believe. But scientists who have devoted a lifetime to the study now conclude that much unexplained nervous apprehension and many intuitive and instinctive fears are inherited from our forbears of the ancient world.

The biologic cell-stuff—or the soul-stuff, whichever it is, that they pass down to us—contains the essence of that thing or that state of mind that makes children and many adults fear the dark, or high places, or snakes, or mice, or running water, or thunderstorms, or being left alone, or mysterious forests, or of being tied up, or of strangers, or fire, or of a hundred other things equally absurd in this protected age.

And these instinctive fears are by no means "imaginary," as so many rugged-minded men and women would have us believe. On the contrary, they are as tangible and definite as is a case of mumps or a broken leg—and they cause infinitely more suffering than either.

Take the fear of darkness, for example. Out of the blackness of a prehistoric night there creeps a great jungle monster. With a roar that freezes the blood he springs among the sleeping clan, breaks the back of the nearest with a blow, crunches the body in his great jaws and snarlingly drags it into the forest. There, for hours, the terror-stricken folk who have sought temporary shelter in the branches of the trees shudder to the carnivora's bloody feast.

The nervous systems of these ape-like ancestors were shocked with an indelibly implanted horror of the dark and its dangers. Is it any wonder that the survivors of these nightly catastrophes transmitted to their children, as part of the inheritance of the race, the instinct to dread darkness and to fear the mysterious shadowy recesses of the forest, where sudden death lurked in the undergrowth?

Is it to be wondered that the deep caves that might harbor ferocious bears, or the black gorges and clefts that were likely to conceal the saber-toothed tiger struck the folk over the heart and caused the thick, reddish-brown hair of their heads to stand on end?

Now, children are nearer their ancestors than we are. Reason, experience, the shame of acknowledging "groundless" terrors and the courage that comes from meeting and overcoming obstacles are not yet theirs. And so they see bears on the black stairs, leering faces peering from shadowy corners, and shapes of dread in familiar daytime objects. The thing that might be under the bed, or in the cellar, or in the murky attic closet—waiting to spring out upon them—is to them as real as is George Washington or the Desert of Sahara to us. And they can no more help being afraid of this old racial memory than we can help fearing death or the tax-gatherer or getting run over.

Practically every child in the world dreads the dark. Even the best-born, the healthiest and the most carefully shielded are liable to sudden stampedes of fear following some suggestion that overwhelms control, and that may actually cause deep-seated, or even permanent nervous disorder.

This fear of darkness is by no means confined to children. Many adults have it to an extraordinary degree. If you don't believe this just have yourself locked into the blackness of a solitary confinement cell for a half hour or so, as I did on the old Australian prison ship that toured these shores a few years ago. I confess, without shame, that I had to keep telling myself that my friends would let me out of this tomb when they got ready. Otherwise I should have yielded to an almost irresistible impulse to kick on that door and to shriek at the top of my lungs. Which, so I was afterwards informed, is exactly the way that nine out of ten behave under these circumstances. The fear of "closeness" complicates the fear of darkness in this instance and intensifies the dread. Our soul-stuff knows that closeness is dangerous and that to be suddenly confronted in a narrow place with some peril which there isn't room to avoid or opportunity to run away from spells disaster.

This knowledge our half-animal forbears have transmitted through all the ages that separate them from us. So, tangled in the woof of inherited instinct are those racial dreads that only time and education and the strong force of example can obliterate—or more properly subjugate—for they are, in my judgment, never obliterated.

Almost as unreasoning as the dread of darkness is the horror of high places. The average person, who has not become immured to it by experience, could not be hired for love or money to walk a girder on the twentieth story, or to balance himself on the coping of even a moderately high building. Some there are who cannot look down a deep well or a subway excavation. Others suffer terribly when they have to go up in elevators or when they cross high bridges or ravines.

Some cannot even watch a steeplejack at work or see some reckless but debonair artisan sliding gayly down a skyscraping rope without getting seasick. Others are frightened, not so much by the height itself as by an almost irresistible desire to jump off when they are up there.

Of course, the slight changes in blood pressure which come with the rise above the sea level, the feeling of insecurity, the "newness" of the situation and the rioting imagination bodying forth the consequences of a "spill," all have their effects upon the body and upon the mind. But back of all these things is that instinctive "gravity fear" transmitted to us by ancestors who didn't fall, but who saw clearly what happened to others who did.

And so, even the tiniest infants, too young to know danger or to have developed any imagination, are sometimes "frightened stiff" at being lifted toward the ceiling or in dropping to the lower floor in an elevator.

Then there is the fear of snakes and of crawling things that possesses ninety-nine out of every one hundred of us. What is there about a harmless little garter snake or a green lizard that should create a panic in women and a murder-lust in men? There is this about it. In the tropical regions that were the first home of the race snakes were almost uniformly venomous. Our geologic ancestors came to know that death sprang upon them from the fangs of serpents. Thus they came to dread snakes and all creeping and crawling things that suggested

snakes. And so they implanted the fear of crawling things in all their children—even unto the ten-thousandth generation.

Now we see why nightmares are so very real—to the one who is ridden by them. And why they so frequently hark back to the horrors that infest the dark, to being smothered by closeness, to falling from tremendous heights, to snakes and all manner of wall-eyed crawling things, and to various other matters in which the individual himself may have no experience, but with which his soul is thoroughly well acquainted.

Our objective or reasoning mind being asleep, the subconscious mind takes the reins and jumps the sleeper over the bundles of horrible experiences. Not content with plaguing us with the frights and fears of ancestral memories, it even manufactures new ones, made up of a most curious and heterogeneous hodge-podge of everything we have heard, smelt, seen, tasted, touched or talked about—generally mixed with some physical sensation that touches the thing off.

For instance, the slipping down of the blankets may start an Arctic exploration expedition, with a whole train of icebergs, seals, walruses, Eskimos, and everything that properly belongs to our conception of what Peary or Nansen must have come through in order to get somewhere near the Pole. Or even such a trivial accident as our poking a couple of toes from under the covers on a cold night may produce a dreadfully embarrassing dream, in which we try to slip unobserved through the crowd on the corner of Forty-second Street and Fifth Avenue dressed in a costume that would make decolleté look like being wrapped in feather beds.

Read Mercutio's beautiful and fantastic description of how dreams are started, and how those so stimulated interpret this stimulus and react to it. For it's true—all but the fairies. And, since Peter Pan, I'm not so sure that they are not true, too.

Perhaps everyone is familiar with the distressing dreams produced by some dietetic indiscretion—the "mince pie" or "midnight lobster" dream. It surely is a realistic and thrilling experience while it lasts, like the drunkard's eulogy of delirium tremens: "You ain't been nowhere and you ain't seen nuthin' till you've had the 'snakes.'"

Yet that little old man with the hideous fanged mouth, who hopped up on your chest and proceeded to grow bigger and bigger and heavier and heavier, until finally, by a superhuman effort, you succeeded in unhorsing him, was only gas. The gas-distended stomach was pushing away for dear life on the diaphragm, compressing the lungs with all the strength of fermentative desperation. The fertile imagination furnished the remainder of the entertainment.

The night terrors of children frequently have a physical cause also. They may originate in "mouth-breathing" and in the defects of circulation which this brings about.

Some nasal obstruction, such as a twisted septum, enlarged turbinated bones, or adenoid growths may block the nasal passages.

Every mother should closely observe her children for symptoms of these conditions. If found, they should be removed. For if they are not removed the child will develop contracted dental arches and other conditions that will prevent the circulation of lymph. Deprived of this nutritive material, the brain will be starved into subnormality, and a child who should be keen and alert becomes a dunce.

If a child cries out in his sleep, or is subject to distressing, restless dreams, see if these nasal conditions may not be the cause. If present, they should be radically removed. The dangers of operation are extremely remote, while the dangers of not operating are immediate and progressive. And the little "tads" rarely outgrow them.

The "falling from a height" dream also has a physical basis of cause when it occurs within the first 45 seconds of sleep. For scientists have shown that this form of "falling nightmare" invariably occurs during the first 45 seconds after falling asleep. It is suggested by the general muscular relaxation that takes place when we settle down to sleep. A change in position of even the fraction of an inch, or the least little slip of the muscles, or any sudden noise that migh suggest slipping or falling is sufficient to convey the idea of a fall to the brain. In the twinkling of an eye the brain has provided precipices, chasms, mast-heads, monuments and divers other things for us to fall or be pushed from, and we "do the rest."

The inherited instincts of fear and the tendency of the mind to translate any unusual sound or motion into terms of danger suggest what is probably one of the most frequent of all causes of night terrors. This is a creaky bed—a bed that rattles, squeaks, moans, groans or protests—audibly or by sagging, or by any other unusual motion—when a sleeper happens to move or turn in his sleep. The very faintest sound or the slightest motion is heard or felt by the subconscious mind. Like a flash it manufactures its dream to fit this particular soul-shock. And it repeats the process possibly hundreds of times a night in response to every unusual move or sound. This, I am convinced, is one frequent cause for nightmare, as well as for light, disturbed sleep, and even for insomnia.

Therefore, a rigid, absolutely noiseless bed all to oneself, for a double bed is an unhygienic abomination that is rapidly becoming extinct, will, in my opinion, do more to banish nightmare than a whole pocketful of pills. And it won't be nearly so hard on the one who has to take it either.

225 West End Avenue.

Immunization of Gravidæ Against Puerperal Fever.—In Bumm's clinic, Berlin, gravidæ are being actively immunized against puerperal fever by the use of a polyvalent vaccine obtained from streptococci present in virulent puerperal sepsis. The results are encouraging.—*Correspondenz-Blatt für Schweizer Aerzte.*

Vaccination and Variola in Mexico.—In the month of May, 1918, nearly 37,000 tubes of vaccine were distributed throughout parts of Mexico by the Federal Health Department. The actual number vaccinated in thirteen municipalities was 6,316, of which 5,230 were in Mexico City. Over one-half had been vaccinated before. The disease is not epidemic and but 21 deaths occurred from this cause in Mexico City for May. But nine patients with variola were interned outside of the city in the hospitals for contagious diseases in the registration districts. In the same area 22 premises were disinfected for variola.— *oletin del Departmento de Salubridad Publica.*

Military Medicine.

WOUNDS OF THE MAXILLARY SINUS IN WARFARE.

WOUNDS of the maxillary sinus in warfare are more commonly the result of missiles. These injuries are not always accompanied by a solution of continuity of the integuments, because it is not rare to find bullets or bits of shell which have penetrated through some other structure and passed through the sinus or become lodged within it, or, continuing their course, have made their exit at some other part of the face or remain embedded. Less frequently the wound is a direct one, with injury to the integuments, fracture of the wall of the sinus, with filling of its cavity with clot. Fractures of the anterior wall are generally comminuted with depression of the fragments.

As complications may be mentioned blood-clot in the sinus cavity or the presence of the missile within it, suppuration with possible necrosis of the walls, and finally at a later date the formation of a fistula. The treatment of such fistulæ is similar to that of empyema of the sinus and therefore offers nothing of particular interest. When the missile has simply traversed the sinus it may produce a very small lesion or there may be considerable destruction of the part. The entire face may be smashed, with extensive destruction of bone and soft structures.

These wounds readily become infected on account of their proximity to the buccal cavity and give rise to a characteristic odor of slough. They should be treated by frequently repeated irrigation with an antiseptic solution. By this means an almost constant antisepsis is maintained, the sloughs become detached, and hemorrhage is not apt to occur. Then the wound granulates and the loss of substance is filled in with surprising rapidity. When cicatrization is complete it is then, and only then, expedient to perform the necessary plastic work.

Very often the maxillary sinuses are wounded by missiles which have penetrated the neighboring structures such as the orbit, nasal fossæ, the face, neck, or even the skull. If these missiles have simply traversed the sinus, no serious damage may be done, or, on the other hand, their passage will cause infection of Highmore's antrum, with resulting fistulæ opening externally, particularly when removal of the missile has been undertaken by the external route. To close these fistulæ, which are usually awkwardly situated, all that is required is to curette the sinus and drain it at its most dependent part. The fistulæ will close in a few days. As to the sinus, it should be attacked at the canine fossa through which it should be curetted and drained. This procedure in most cases will be completely successful.

The most common complications are suppurative processes, necrosis, and fistulæ to which reference has already been made, but there still remains hemorrhage, which although not common may be of extreme gravity. This occurs particularly during attempts at extraction of the missile when the latter is lodged in the cavity of the sinus. Plugging is often not enough to control the loss of blood, in which case one should not hesitate to ligate the external carotid. This is the only means of preventing secondary hemorrhage which may arise when the sloughs are eliminated. Some of these secondary hemorrhages may be really fearful and probably came from a wound of the internal maxillary artery or of one of its larger branches. In such cases no time should be lost by plugging, but the external carotid should be tied without delay.

Serotherapy of Gas Gangrene.—Two years ago the attempt was made to inject at once into the surrounding tissues in a gas gangrene wound some of the patient's own discharges pending a bacteriological examination and also because the variety of the bacteriological flora made it very doubtful that a proper serum could be manufactured for the individual case. The idea seems to have come from the French veterinaries who, in turn, doubtless derived it from our own veterinaries, while the latter evidently obtained the idea from Dr. Duncan of New York. The results of this autotherapy of gas gangrene were said to have been encouraging, but the hope was expressed that straight specific or polyvalent serotherapy could be made to fit the condition. Last July there was an extensive discussion of the subject before the Société de Chirurgie, reported in *La Presse Médicale* for July 25. The subject of autotherapy was not discussed, for the reason that we are now pretty certain as to the identity of the pathogenic organisms and can antidote the worst of them with stock preparations (serums). Weinberg and Seguin, who made the autotherapy experiments, have sera to antidote the perfringens, the edema bacillus, and the septic vibrio, and a mixture of these sera has been used as a preventive in recent wounds which promise gangrene. In fifty wounded thus treated none developed gangrene. The surgeons who report the use of the serum are Duval and Vaucher. The work was then extended to other types of wounded and the injections were made at a later period. In but one series, of four cases of neglected and putrid wounds, did cases of gas gangrene develop despite serum. Professor Delbet, who had officially brought the subject of the autoserotherapy of gas gangrene before the Société de Biologie in 1916, recommended the use of the trivalent serum for prophylaxis. Bazy mentions a quadrivalent serum, a serum of the *Bacillus bellonensis* being added to the first three mentioned. However, he regards the septic vibrio and the perfringens as the chief offenders. He also mentions the possibility of increasing the valence by adding ordinary streptococcus polyvalent serum. Rouvillois and others favor a mixture of vibrio and bellonensis for routine use, as already recommended by Sacquépée, with special reference to the cure of gangrene already present. In five cases of this type death took place later from the consequences of amputation, the surgeons unanimously insisting on the most radical surgical intervention in association with serum therapy. In another series of cases with such intervention recovery occurred and finally there were a number of recoveries in non-operative cases.

Mentally Deficient Recruits for the Army Service.—Captain O. C. I. Withrow, C. A. M. C., writes

in the *Canadian Public Health Journal*, March, 1918, concerning mentally deficient recruits, as follows: The problem of the unfit is of more concern in army circles than in the civilian community. War is a hard taskmaster, and is insatiable in its demands. It cannot brook physical disability; it must have the best. Moral disability is no bar to entrance into the ranks; all war asks is a sufficient morale in its gregarious fighting humanity. The question of mental disability is both important and difficult of solution. It presents grave difficulties because of the lack of time to institute a proper examination of mental capacity. The idiot and the low-grade imbecile present no real problem. The brand they wear is deep enough and plain enough for a real decision at a casual glance; but the high-grade imbecile and the moron with the victim of a psychosis are often passed through training. It is not surprising that this should be, for they have sufficient intelligence to answer all necessary questions and the elucidation of their malady would require a different line of tactics by the medical officer. In the early days of the war men were so eager for acceptance that they hid their disabilities if possible. Now recruits are so eager to recount their numerous maladies that it is surprising that one small human body can carry such a conglomeration of complaints. This refers more especially to the physical. The mental problem is the same now as then. The men themselves do not know their disability and even their friends are loath to admit the possibility of any such blight as mental deficiency or insanity. Thus the medical officer, having little to guide him, ofttimes stumbles and falls upon a very rocky road. For there is no shadow of doubt that mental defectives give great concern to a medical officer of a unit so soon as they have donned their uniform. Every fellow may look alike in khaki, but every man does not act like his comrade, any more than do the units in civilian life. Defective mentality shows itself early or late. The greater the deficiency the sooner the discovery. One mental defective in a platoon may cause more anxious thought than all the rest of the men, while physically he is so fit that the mess hour is hardly sufficient to satisfy the call of an abnormally healthy appetite. This class of man is not understood and numerous crimes stand to their discredit, while punishment has no efficacy whatever as a corrective. If these men were properly understood they might prove fairly useful servants at certain duties, but the gain therefrom is offset by the loss of such valuable time and money that it is better to shut the entrance gates to them, or if, perchance, an odd one slips through discerning medical boards to have his name deleted from the roll as speedily as his symptoms become manifest. Withrow believes it would be good policy to have a board of two competent psychiatrists at the center of every military district, to whom suspected cases of mental deficiency and psychoses be referred. It takes time to make a diagnosis and the importance of a diagnosis is threefold. 1. It is not fair to the recruit to stigmatize him as a mental case if he is not such a one. 2. It is not fair to the fighting forces at this time to keep out of service one possible addition to the ranks because he may inadvertently have been labeled mentally deficient. 3. It is not fair to the government nor is it good business to carry one single mental defective on the rolls of the forces one moment longer than is necessary for a proper diagnosis. It appears to Withrow that the parties concerned might be fairly dealt with. Many loyal and devoted persons have expressed their conviction that it seems a great pity to send all the physically fit to fight our battles with the prospect of death or disfigurement, while those of lesser physical attainments are left at home. It seems a great hardship that we leave behind the mentally defective while those of brighter intellect march off to do exploits. But what will you? War is war, and it takes the keenest and the bravest to stand the rigors of a campaign and one deficient intelligence may cause a cataclysm of disaster in the very hour of expected triumph.

Hydrotherapy in the Treatment of War Injuries.—Hydrotherapy, according to R. Tait McKenzie (*American Physical Educational Review*), plays an important rôle in the treatment of the wounded man, as it has the additional resource of cold as well as heat. The cases that derive most benefit from hot water are those marked by great areas of contracted scar tissue, painful stumps, and weakened and stiffened joints. Slight adhesions may be broken down frequently, after its use, and all parts are more easily manipulated. Irritable bruised nerves are made worse by heat so that for them the bath should not be raised above 100° and manipulation or massage should never be used, the water should here act as a comforting poultice. A sort of gymnastics of the circulation is given by the alternate use of hot and cold water in the Scotch douche or the local contrast baths advocated by Sir Robert Jones. The full sedative bath at 94°, lasting for an hour, is of great value in shock. The whirlpool baths, first used in France during the war, are the most valuable single appliance in the after-treatment of wounds. The arm or leg is plunged into a vessel containing water at about 105°, which is circulated by jets set at an angle, or by a propeller. Air is also introduced so that the limb is surrounded by a swirling, bubbling current, the temperature of which is raised as high as 120° if the patient can bear it. The air bubbles increase the stimulant effect on the skin and the heat is applied to the surface far more surely by this means than if the water were still. These baths are particularly effective for painful stumps, painful scars, partial paralysis, or in fact for any condition which lowers the circulation and nutrition of the member. The period of treatment is about twenty minutes and the patient, made warm and comfortable, is then ready for massage and manipulation, which could not have been performed without this preparation.

New York Committee of the Volunteer Service Corps.—The Central Governing Board of the Volunteer Medical Service Corps of the Council of National Defense announces that the New York State Executive Committee of the Volunteer Medical Service Corps is comprised of the following

doctors: George D. Stewart, New York City; John Van Duyan, Syracuse; Gilbert D. Gregor, Watertown; J. I. Dowling, Albany; James B. Clemens, New York City; Charles G. Stockton, Buffalo; John E. Virden, New York City; J. E. Wilson, New York City; Walter B. James, New York City; W. Stanton Gleason, Newburgh; Walter F. Chappell, New York City; Joseph W. McGill, Rochester; Nathan E. Brill, New York City; James S. Waterman, Brooklyn; DeWitt H. Sherman, Buffalo; William M. Brown, Rochester. The purpose of this committee is to co-operate with the Central Governing Board in prosecuting all activities pertaining to the mobilization and enrollment of members of the Volunteer Medical Service Corps throughout the state. The Central Governing Board of the Volunteer Medical Service Corps also authorizes the appointment of one county representative in each county in every state of the Union. The county representatives for New York are F. E. Sondern, New York County; James C. Hancock, Kings; J. Lewis Amster, Bronx; William Bryan, Richmond; J. J. Kindred, Queens.

Women Anesthetists Wanted for the Army.—It is announced that there is need of competent women anesthetists and a call has been issued asking that all women physicians who are qualified for anesthetic service or who are competent to be intensively trained communicate at once with Dr. F. H. McMechan, Avon Lake, Ohio.

Health in Army Camps.—A statement issued by the War Department on September 19 reports that the health of American troops at home and overseas continues good. For the two-month period ended August 31 the death rate of the entire Army was 2.18, compared with a death rate of men in civilian life of military age of 6.7. For the week ended September 20 there were 108 deaths at all camps as compared with 95 for the previous week. There has been a rapid spread of Spanish influenza among soldiers in training, with epidemics at Camps Devens, Massachusetts; Upton, New York; Dix, New Jersey, and Lee, Virginia; the Great Lakes Station, and the Second Naval District, Newport, R. I. It is expected that the disease will appear at other camps and cause a general increase in the sick rate. On September 20 fifteen deaths were reported from pneumonia developing from influenza among soldiers at Camp Devens. While this is the largest number of death reports for a single day, camp authorities state that the epidemic is waning and that the number of cases admitted to hospitals daily is decreasing. A report given out by the War Department on September 23 announces that up to noon of that day there have been reported 20,211 cases of influenza in the various Army camps. Seven camps reported influenza cases for the first time on this date. The epidemic continues most severe at Camp Devens, Mass., the total number of cases reported from this camp to date being 10,700. Camp Dix, N. J., ranks second with 1,897 cases to date. At Camp Devens the number of pneumonia cases is high, 424 new cases having been reported from September 19 to 23. For the previous two weeks the average number of cases per week was 45.

Training of Hospital Assistants.—The following resolution was unanimously adopted at Washington on September 20 by a special committee which included Col. Winford H. Smith, Surgeon General's Office, chairman; Miss Clayton, League for Nursing Education; Miss Crandall, Committee on Nursing, Council of National Defense; Miss Delano, American Red Cross; Dr. Goldwater, War Service Committee, American Hospital Association; Miss Goodrich, Army School of Nursing; Miss Nutting, Committee on Nursing, Council of National Defense; Miss Thompson, Army Nurse Corps:

Resolved, That civil hospitals which have the necessary facilities be encouraged to arrange for the training and use of hospital assistants according to the plan and qualifications of the Army School of Nursing.

That such hospital assistants should be enrolled through the American Red Cross, with the understanding that they will accept service, as required, either (*a*) in the hospitals in which they are trained, (*b*) with the American Red Cross, or (*c*) in Army Hospitals.

American Clearing Hospital Shelled.—After throwing a large number of high explosive projectiles into the region of an American clearing hospital on the Lorraine front for two successive nights, a large tent where gassed patients were confined was struck on the night of September 9. Eight Americans, the majority of them privates, were killed outright and several members of the medical corps were injured. This attack, like many previous ones of a similar nature, was evidently intentional and deliberate, as the roof of the hospital was marked by a large red cross.

New Hospital for Shell Shocked Soldiers.—Dr. John T. M. Finney of Baltimore, surgeon in chief of the American Expeditionary Forces, who recently made a brief visit to this country, has returned to France after having secured a large appropriation from the Federal Government, which places at his disposal several millions of dollars to erect and maintain a hospital in France for the treatment of shell-shocked American soldiers.

American Women's Hospital Sends Second Unit.—The second unit of the American Women's Hospitals, which will be added to the staff of the military hospital, at present working with the Sixth Army Corps in cooperation with the American Committee for Devastated France, has sailed. This hospital contains 100 military beds, with capacity for expansion, and also has a small civilian ward. The unit which has sailed consists of Dr. Caroline M. Purnell, Philadelphia; Dr. Mary L. Evans, Middletown, Conn.; Dr. Charlotte Fairbanks, St. Johnsbury, Vt.; Dr. M. Ethel Fraser, Denver, Col.; Dr. Mary MacLachlan, Portland, Ore.; Dr. Ier Jay Manwarring, Norwich, Conn., and a corps of nurses. Dr. Purnell will act as special commissioner for the American Women's Hospitals in France.

New Hospital for Camp Mills.—As Camp Mills is soon to become a permanent cantonment, in addition to the construction of permanent barracks, work has been started on a new hospital which will furnish accommodations for 2,000 patients.

THE FOURTH LIBERTY LOAN.

ALTHOUGH as a body the medical profession has made greater sacrifices than any other calling, sending a larger proportion of its numbers to war than any other class in civil life, it nevertheless remains for those of its members who cannot give actual military service to do their part back here. In an article in this issue Dr. Kindred shows why physicians, especially those of us who are prevented by age, illness, or other impediment from going to the front, should do their bit for the success of the new Liberty Loan offered this day. The army surgeon is not a fighter—much as he might like to be—but he is as essential to the success of our cause as any one on the firing line; and we, his colleagues far in the rear, neither can we fight, but we can make our work tell as effectually as he, though in a different way. We, too, can make sacrifices. We have not given up our practices, but we can give up the income, as much as possible of it, derived from practice to equip and pay our brothers who are doing the actual work.

There is another reason why we should do all in our power to aid our country in its struggle against the cruelest and most fiendish of enemies ever recorded in the history of warfare; not only are we impelled by patriotism to help, but we are further called upon as a profession to make expiation for the inhumanity of many German army surgeons, whom we once honored with the title of colleague, but who have disgraced themselves and their profession by their brutality and cowardly ruffianism. Many instances of unprofessional conduct by German army surgeons are on record, but we need only mention Wittenberg, where Dr. Aschenbach and his staff neglected the prisoners so shamefully and then ran away as soon as a few cases of typhus appeared, leaving the care of the sick and the sanitation of the prison camp to several English surgeons among the prisoners. For the honor of our profession therefore let us do our part to make the Liberty Loan a success, and then buy more bonds in order to atone as far as we can for such crimes as have been committed by our enemies in attacking hospitals and hospital ships, and especially by those German doctors, who are few we try to believe, that have displayed such brutality in their treatment of wounded prisoners.

Next week, through the generosity of many of our advertisers, further urgent appeals will be made to the humanity and patriotism of our readers, but one need not wait for that. Let us buy what we can at once, and perhaps the appeals of next week will persuade us that it is possible to buy still more.

THE "MYTH OF ANAPHYLAXIS."

AUTHORITIES continue to insist on the necessity of large doses of serum in the treatment of diphtheria. There should be no hesitation, no scruples, they say, to swerve the practitioner from his duty in this respect. Nor should the patient shrink from his duty in the same dilemma. In this connection the subject of anaphylaxis at once looms up as the chief deterrent in practice. Jousset, in an article which appears in *La Presse Médicale* for August 5, gives his experience and convictions concerning the alleged peril of anaphylactic shock. He has long been accustomed to give large doses of serum in tuberculosis. He has often enough seen the phenomena of anaphylaxis, innocently produced, but never were these serious in character, and he has had opportunities for an unbiased study. To assume that sera are dangerous is to warp the judgment. In his tuberculous work he has had to employ large doses of increasing size, yet he knows nothing of that famous bugbear which is the terror of the practitioner. He begins with a dose of 100-150 c.c. and often reaches a total dose of a pint, a quart, and even more. Aside from the local reaction, which is more apt to be excessive with the high dose, the percentage of seric accidents is but little larger with the high than with the small and medium dose. Hence anaphylaxis is not to be regarded as a matter of dosage. The eruptions are aggravated by large doses and are, perhaps, threefold more pronounced; but to renounce large doses for this reason would be like failing to give a malarial subject the benefit of quinine because of some collateral action of that drug. The author continues to berate the phantom of anaphylaxis, "that caput mortuum of serotherapy." No doubt the word covers up much ignorance and all obscure and mysterious untoward phenomena are laid at its door. Because of "anaphylactophobia," Jousset says, many a life has been lost. He goes so far as to assert that there never has been a well-recorded case of fatal or severe anaphylactic shock due to repeating a serum injection. He asks to be shown that he is mistaken in this claim. He limits the subject to subcutaneous injections, the kind almost always practised. He has made more than 1,500 such injections and has yet to see a case. He admits that after intravenous injections—of salvarsan, for example—and without reference to previous injections, alarming crises have developed; but upon analysis these do not resemble

Richet's anaphylaxis. It is evident that anaphylactic shock must be instantaneous, but the severe reactions which follow intravenous injections may appear only after the lapse of hours.

The fact of previous sensibilization, which is the very essence of the anaphylactic phenomnon and which alone makes the phenomenon intelligible, is found on analysis of reported cases to be nonexistent in the majority—in other words, the phenomena, whatever else they may be, are not even anaphylactic, but come under the head of serum sickness. What then becomes of anaphylaxis in medical practice? We see here only the simple operation of a toxin—not a general property on the part of the serum but an individual intolerance. The latter is conceivably of the same nature as individual intolerance to foods of a certain type. Let us, therefore, Jousset insists, speak of serum intolerance and not of anaphylaxis. The bugbear of anaphylaxis has to do solely with the repetition of an injection and if the subject has shown no intolerance to a first injection we need have no fear of repetition. The author's chief dread in serotherapy is of Arthus's reaction—a local phenomenon—and this because of the possible development of a phlegmon. This is positively the only accident the author fears, because it can neither be foreseen nor prevented. But this phenomenon is not due to intolerance of an individual character. It is an artifact, so to speak, and to be charged up largely to defective technique. The size of the dose cuts no figure, but it is a phenomenon of repeated injections, which explains why it is erroneously classed as a local anaphylaxis. With certain precautions it should not be seen oftener than once in fifty subjects.

PHTHISIOPHOBIA AND PHTHISIOMANIA IN FRANCE.

In the *Journal de médecine et de chirurgie pratiques* for March 25 is an abstract of an article by Lereboullet which deals with the fear of tuberculosis as a menace to the expeditionary troops exhibited in some quarters of the United States. This fear is based on exaggeration of the effect that 400,000 French soldiers have been invalided home for that affection since the beginning of the war. This figure is over four times too great, and so far from reflecting the condition of the army is an index to the prevalence of the disease in the nation. With this number deducted the army *per se* cannot be regarded as visited with the disease. Up to November 1, 1917, of the more than 89,000 evacuated for the disease, by no means all were actually tuberculous, for there was a considerable percentage of wrong diagnoses. Moreover, at least 65,000 eliminated during the first year must have contracted the infection before beginning military life. Of the remainder there is no evidence that any of them were infected during the war, for we know that in the vast majority of cases the disease is awakened from a latent form as a result of military hardships.

The problem of rendering the tuberculous soldier innocuous to the civilian population after he has been retired from the army, and after the end of the war, will be greatly aggravated by a widespread fear of infection. The establishment of sanatoria in this or that community—naturally, certain sites with climatic advantages will be chosen—is always resented by the resident population. His own relatives, who must care for the victim, often exhibit the same fear, and practical isolation under the tender mercies of a hired keeper is the result. Examples cited by the author illustrate the morbid fear of the disease even by a parent or spouse, and the one idea is to pass the burden along to some one else. In such kinsfolk the phobic state completely ousts all altruism and family attachment. The expressions of fear recall those manifested toward lepers.

Phthisiophobia may pass on to the condition of phthisiomania. In the former the subject is morbidly anxious to avoid infection; in the latter he believes that despite all care he has become infected. He no longer fears others, and no amount of assurance that he is still intact can prevail over his mental state. Some of these subjects may have had tuberculous affections at some period, and believe that reawakening has occurred. Only a campaign of education can change these points of view.

SERGENT'S WHITE LINE IN SOLDIERS.

According to an abstract in the *Journal de médecine et de chirurgie pratiques* for July 25, Baudron has conducted a special research for the presence or absence of this phenomenon in 100 sick or wounded soldiers in a garrison infirmary. The technique was carried out in the usual manner, the skin of the abdomen being stroked gently with some blunt object—for example, the pulp of the finger; a slight pressure is necessary. At the expiration of a few minutes one sees the appearance in the track of the finger of a white streak, which increases in distinctness until a maximum is reached, remains stationary for a longer or shorter time, and then slowly effaces itself. The interpretation of this line has led to controversy, and it was to throw more light on the subject that the research was carried out. Military exigencies are also much more favorable for the occurrence of conditions which favor the development of the line than civil life, for there we find constantly states of infection or intoxication in combination with overwork and fatigue. In the hundred subjects examined the line was elicited in 81. It was present in all, but two of the following febrile cases and in 17 out of 20 subjects with gonorrhea. It was never absent in grip, rheumatism, malaria, or tuberculosis, and was encountered in a variety of purely local conditions, as gingivitis and orchitis. The conclusions of the author concerning the white line are as follows: It is of great value in certain emergencies of differential diagnosis, as when acute adrenal insufficiency is confused with a pyrexia of meningeal, thoracic, or abdominal origin.

Its association with certain infections like grip and rheumatism means a certain degree of asthenia and hypotension, and betrays the implication of the adrenals in the disease picture. Here it does not indicate a serious state of affairs in comparison with the severe syndromes of acute adrenal insufficiency, with collapse, and does not carry a bad prognosis. Finally, when encountered in association with some trivial local condition, it represents a mere coincidence, or is due to a transitory disturbance of vasomotor equilibrium.

Some Brazilian Pathology.

In the *Brazil-Medico* for March 2, Villela reports the first case of acute Chagas' disease to be seen in the State of São Paulo. The patient was a boy aged 16 months, member of a goitrous community, and presenting evidences of myxedema. There was a generalized lymph-node engorgement, enlarged liver and spleen, and slight bronchitis. There was an ulcer over the right hip with a few scattered vesicles. The diagnosis was confirmed by blood examination, the *Trypanosoma cruzi* being recognizable therein. De Rezende reports a case of leishmaniasis of the nasal fossæ in a boy of 16 years who had developed a pimple behind one of his nostrils 8 months before. In the interim, ulceration proceeding therefrom had completely destroyed the cartilaginous septum and had transformed the area of the nostrils into a large ulcer. The extension of the process into the nasal fossæ had blocked them so that the patient breathed wholly through his mouth, which was held constantly open. Despite his predicament the lad's general health was excellent, and he ate with good appetite. The first diagnosis was syphilis, although the history and collateral evidences were negative. The treatment test having likewise proved negative, the alternate diagnosis was leishmaniasis. The author treated the case with a mixture containing arsenic, antimony, methylene blue, quinine, etc., which is used in the hospital as a purely local application, and obtained a complete cure. Apparently there were no injections of antimony practised. At a later period four cases of so-called Baurú ulcer which had appeared in the hospital received the same treatment, with the same brilliant results. These lesions are usually regarded as a form of cutaneous leishmaniasis. Silva Araujo, Jr., presented a case of so-called boubas before the Brazilian Dermatological Society. The patient was a boy of 17, and the eruption was of 3 months' duration. He knew of 5 similar cases in his vicinity. The primary manifestation was on the dorsum of the foot. There was a general reaction, with headache and pains in the bones and an outbreak of frambesiform lesions over most of the surface. Smears from the lesions revealed the presence of the *Treponema pertenue*. The patient recovered promptly on sodium iodide.

"Soft" Drinks for French Workmen.

According to an abstract in the *Journal de médecine et de chirurgie pratiques* for August 10, an attempt is being made, or at least suggestions have been made, in favor of substituting alcohol-free beverages for the workingman's red wine. There are, of course, the classic drinks—tea, coffee, cocoa, lemon juice, and licorice beverages—but recently others have come to the front, such as the so-called "red drink," which is a non-alcoholic wine. Instead of making grape juice outright, an extract of claret is prepared which conserves its flavor, and to this is added artificially colored water, so that we have a near wine, or "vinoline," which is quite analogous to the near-beers of the United States. Another beverage recommended is "frenette," made from the dried leaves of the ash by decoction. This may also be used as a mildly alcoholic beverage by fermenting it after addition of a little sugar. The amount of alcohol desired is not over 18 grams per liter, or less than 2 per cent. This drink may be prepared on a considerable scale by making it in a cask. Fermentation is under way in two weeks, and the mixture is then allowed to stand a week before bottling. The only object in fermenting and thus alcoholizing this drink is the production of gas, for a drink that foams always has the preference over a still one. The author admits that the same result can be obtained by artificially charging with gas, but perhaps this necessitates apparatus which the other way can dispense with.

Bacteriology of Vernal Influenza.

It is entirely conceivable that in the course of a pandemic the bacteriologists of one country might be more favored by chance than those of others in the recognition of the presence of organisms, especially of new microorganisms, in the secretions of the victims. This applies also to the discovery of old germs in new rôles. We note that in the present pandemic, after much report of negative results, authors are beginning to announce positive finds of pneumococci and microorganisms. In Italy, in the latter part of May, the troops were attacked with what was apparently pappataci fever. At a later date this view was changed and the epidemic was pronounced to be influenza, in which the offending microorganism was the tetragenes. The latter was found in the blood, in pleural exudate, etc. According to an abstract in *La Riforma Medica* for July 20, Saccone made blood cultures of 120 soldiers at various days of the fever. Nothing was found after a certain interval had elapsed, but in the first day or two of the disease positive results were obtained in about half the cases tested. The organism was in the grouping of both the tetragenes and diplococcus, and also was seen isolated and in chains. It took the gram stain readily. By reason of its variation from the ordinary tetragenes the author terms it the "*Micrococcus metatetragenes* of vernal influenza."

News of the Week.

Influenza.—The New York City Board of Health at its regular meeting, on September 17, placed pneumonia and influenza on the list of diseases that must be reported to the Health Department by all physicians. Patients are being quarantined and those so situated that an effective quarantine is not practicable may be compelled to go into hospitals. The bacteriologists of the Health Department in their study of the cases find the Pfeiffer bacillus in a large percentage of the cases and in addition

a minute organism which as yet has not been identified. Up to September 20 about 450 cases of influenza have been reported to the New York City Health Department. A report from Boston shows that on September 17 there had been within twenty-four hours seventy deaths from influenza, including three naval men, and twenty-seven deaths from pneumonia, and that there were several thousand cases of the disease in that city. Later reports announce the appearance of the disease in Washington, D. C., and in Chicago. The Surgeon General of the Public Health Service has issued rules to the public to safeguard against the spread of respiratory diseases, which lay emphasis on the importance of personal cleanliness, good hygiene, fresh air, and the avoidance of unnecessary crowding.

Health Department Makes Changes in Administrative System.—Changes in the administrative system of the New York City Health Department have been announced, having for their purpose the coordination of the work of the department and the granting of autonomy to the boroughs. The chief officer in each borough, now called the Assistant Sanitary Superintendent, will become the head of that borough. All the employees in a given borough will be under the direction, supervision, and control of the Assistant Sanitary Superintendent. It is understood, however, that except in cases of emergency each employee, now or hereafter assigned to a borough office for the work of a given bureau, will not be taken from that particular work without orders from the Commissioner's office. There will be attached to each borough office, as is the practice at present, a representative of each of the bureaus of the department requiring field representatives. Questions of policy, exceptional conditions, and changes in personnel will be brought to the personal attention of the Commissioner, who will make final decision in cases of disagreement between the Sanitary Superintendent and the head of any borough. The entire detail of the new plan has not yet been made public.

Women Doctors Raising Fund for Hospital.—The women physicians of the New York Infirmary for Women and Children are conducting a campaign to raise $200,000 for this institution. Dr. S. Josephine Baker is chairman of the campaign committee and has enlisted four hundred volunteer workers in this movement.

Dr. Charles Duncan of Concord, N. H., has been elected secretary of the State Board of Health to succeed the late Dr. Irving A. Watson.

Dr. J. G. Henry has been appointed epidemiologist for the city of New Haven, Conn.

Dr. Abraham Jacobi of New York had a narrow escape on the night of September 20 when his summer home at Lake George was destroyed by fire. According to press reports, the part of the house in which Dr. Jacobi had his sleeping apartments was cut off by flames and Dr. Jacobi, who is 88 years of age, jumped from a second story window, fortunately sustaining no injury more serious than a few bruises and cuts on the arm. A number of letters and manuscripts, including the first chapters of an autobiography, were destroyed. We congratulate Dr. Jacobi on his most fortunate escape and wish that he may yet have many peaceful years in which to rewrite and complete the autobiography which has had such troubled beginning.

Major Joseph B. Bissell, Surgical Director of the New York Radium Institute, has been assigned to active duty in Maryland. Dr. C. Everett Field, Medical Director of the Institute, still remains in charge of the routine work. Although several of the regular staff have been drawn into the service, all cases of malignancy referred for radium treatment are being admitted.

The Boston University School of Medicine.—Boston University announces that its medical department has been thoroughly reorganized and henceforth will be non-sectarian in scope and character. Regular physicians will conduct courses in pharmacology and therapeutics and clinical teaching will be given in the Boston City Hospital and the Robert Bent Brigham Hospital. Homeopathic materia medica will be taught as heretofore, with clinical teaching in the Massachusetts Homeopathic Hospital and allied institutions.

Henry Street Settlement Work.—This institution, which supplies visiting nurses to the needy of Manhattan, has just made public its annual report on the activities of its twenty-fifth year, together with plans for the further expansion of its work. The increase of illness among children due to undernourishment and inadequate heating has greatly increased the demands on the visiting nurse. The expenditure of the year amounted to $158,928, against an income of $135,876, and special efforts are being made to wipe out the deficit thus created. During the year covered by the report the settlement nurses cared for 32,753 patients, making 277,179 visits. In order to provide for the expansion necessary to meet the increased demands on the service it is proposed to raise a million dollar fund to pay salaries and expenses of nurses at home, to erect a central administration building for the nursing service, and to train a larger body of student nurses.

The Wesley M. Carpenter Lecture.—The New York Academy of Medicine will hold its first meeting of the season on Thursday evening, October 3, at 9 o'clock, at which time Prof. Graham Lusk, one of the representatives at the recent meetings of the Interallied Scientific Food Commission abroad, will deliver the Wesley M. Carpenter Lecture, his subject being "The Scientific Aspect of the Interallied Food Situation."

The Ohio State Medical Association will hold no meeting this year. The seventy-third annual meeting was to have been held in Columbus during the first week in October.

Health Department Gives First Aid Lectures.—The New York City Commissioner of Health has made arrangements for a course of lectures on first aid and similar topics for the employees of the Health Department and the public generally. The first lecture of the series, delivered on September 11, was on "First Aid from the Fire Prevention Engineer's Viewpoint." The second lecture was delivered in Room 526, Municipal Building, on September 18, on "First Aid in Resuscitation," by Commodore Charles E. Raynor, United States Life Saving Station.

Gifts and Bequests.—The will of Marie Louise Tillotson makes the following bequests to local

charities: Society for the Relief of the Destitute Blind, $20,000; Post-Graduate Hospital, $10,000; New York Eye and Ear Infirmary, $5,000; New York Society for the Relief of Widows and Orphans of Medical Men, $5,000; Tuxedo Hospital, Tuxedo Park, N. Y., $5,000.

Under the will of Dr. Sidney L. Spiegelberg of New York, who died recently at Bussey-le-Chateau, France, while serving in the American Army, the decedent's life insurance, amounting to $500, is left to the New York Physicians' Mutual Aid Association.

By the will of the late Emma Goldbeck of Philadelphia, the sum of $1,000 is bequeathed to the Children's Homeopathic Hospital of that city.

By the will of the late Annie Fassett of Philaphia bequests are made as follows: Rush Hospital for Consumption and Allied Diseases $10,000; Children's Seashore Home for Children at Atlantic City, $1,000, for a free bed and $1,500 for a free bed for a mother and child.

The will of the late Lillian E. Koenig of Philadelphia disposes of an estate of $6,000, out of which sufficient is to be set aside for the endowment of a bed in a hospital as a memorial to her mother and father.

New Clinics for Mothers. — The Maternity Center Association of New York City has decided to open three new clinics in different parts of the city. These will be operated at 72 Market Street, 169 Mott Street, and 36 Manhattan Street. The association has for some time past been conducting fifteen clinics and reports that its work has grown enormously during the past few months.

Addition to Peekskill Hospital.—A campaign is being conducted for the purpose of raising a fund to build a memorial wing to the Peekskill Hospital in memory of the seven volunteer firemen killed recently at a fire at the Fleischmann plant in Peekskill. Thus far $12,000 has been subscribed.

Leper at Large.—John Early, a leper, who several years ago attracted considerable attention by his efforts to retain his liberty, is reported to have escaped from a detention house on the outskirts of Washington and has thus for evaded capture.

Obituary Notes.—Dr. JOHN H. DEMAREST died at his home in White Plains on September 14, at the age of 80 years. He was a graduate of the New York Homeopathic Medical College in 1865, a member of the American Institute of Homeopathy and the New York State Homeopathic Society. He was connected with the Metropolitan Hospital on Blackwell's Island for thirty years.

Dr. MOTT DWIGHT CANNON of New York and Greenwich, Conn., died suddenly at Poultney, Vt., on September 21, aged 59 years. He was a graduate of the New York Homeopathic Medical College in 1882.

Dr. JOHN DALLAS ERDMAN died at Allentown, Pa., on September 6 as a result of injuries received in an automobile accident. He was 62 years of age and had been president of the Allentown Board of Education. He was graduated from the medical department of the University of Pennsylvania in the class of 1872. He was a member of the Lehigh County Medical Society and of the Medical Society of the State of Pennsylvania, and a Fellow of the American Medical Association.

Correspondence.

CONSERVATION OF PLATINUM THROUGH PHYSICIANS AND DENTISTS OF THE COUNTRY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: As you know, there is a great stringency in the platinum situation at this time, and it is necessary to employ every possible means to secure a supply. You will, therefore, contribute to the war program by publishing in your journal the following open letter to the doctors and dentists of the country:

In view of the limited supply of platinum in the country and of the urgent demand for war purposes, it is requested that every doctor and dentist in the country go carefully over his instruments and pick out *every scrap of platinum* that is not absolutely essential to his work. These scraps, however small and in whatever condition, should reach Governmental sources without delay, through one of two channels: (*a*) They can be given to proper accredited representatives of the Red Cross who will shortly make a canvas for that purpose. (*b*) They may be sold to the Government through any bank under the supervision of the Federal Reserve Board. Such banks will receive and pay current prices for platinum.

By giving this immediate attention you will definitely aid in the war program.

It is recognized that certain dental and surgical instruments requiring platinum are necessary, and from time to time platinum is released for that purpose. It is hoped, however, that every physician and every dentist will use substitutes for platinum for such purposes wherever possible.

You are warned against giving your scrap platinum to anyone who calls at your office without full assurance that that individual is authorized to represent the Red Cross in the matter.

Lieut. Col. F. F. SIMPSON, M.C., N.A.,
Chief of Section of Medical Industry.

HOW TO TREAT A COLD SIMPLY AND EFFECTIVELY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR: In the course of a lifetime I have had colds to treat at all ages and under different circumstances. I have tried a great many remedies. At present I offer the following as being the best I know.

As soon as the first premonitory symptoms of a cold manifest themselves, such as sneezing, chilliness, cough, give from 5 to 10 grains of salicylate of ammonia and one-half a grain of caffeine every two hours, for four to six doses, as an adult dose, in capsules or konseals. If it be a child give appropriate dose in solution, with a little syrup of tolu and peppermint water. In many instances the cold will be aborted, or abridged in length and severity. The cold may signify little but passing discomfort, or it may mean the beginning of grippe, bronchitis, or pneumonia. In any event, the salicylate and caffeine are very useful, and sometimes ward off or greatly ameliorate impending trouble.

If there be fever in the beginning, or within a few hours, add one-half to one grain of phenacetin to every dose of salicylate, for an adult. At bedtime stop salicylate and caffeine and take one-half teaspoonful of aromatic spirit of ammonia and one-half teaspoonful of sweet spirit of niter in two tablespoonfuls of water. If the nose is stopped up, or running, with or without sneezing, use a little one per cent. carbolized vaseline or a menthol salve.

The comfort and well-being of a patient, when distressed with nasal obstruction, frequent cough, fever, and general malaise, is much promoted by a hot mustard foot bath, later drying the feet thoroughly and putting on a long pair of woolen stockings, such as golf players wear, and then to bed, with much covering at first to promote perspiration. Of course, if there be constipation a laxative pill after breakfast or a Seidlitz powder before is indicated and desirable.

Whenever the cough persists, with expectoration, stop the use of salicylate and caffeine and give syrup of hypophosphite of ammonium, a teaspoonful every two hours, just as it is, and wear the perforated zinc inhaler, making use with it of equal parts of beechwood creosote, spirit of chloroform, and alcohol. At first, the inhaler should be worn a few minutes at a time. Later it may be worn an hour or more at one time, and repeated several times in twenty-four hours.

Painting the chest with compound tincture of iodine, or rubbing it with equal parts of spirit of turpentine and compound soap liniment, is useful, and either one may be employed, according to the convenience or choice of the patient. If there is notably localized pain in the chest, the use of the electric pad is often most comforting especially at bedtime.

If there is marked fever, with cough, and pain in the chest, bed should be insisted upon, and warm inhalations of creosote vapors from a croup kettle should be begun and kept up more or less continuously until the symptoms have greatly improved. If the creosote odor is objectionable it may be modified by the addition of compound tincture of benzoin, or one of the oils of pine, like *oleum pini sylvestris*, or *oleum pini pumilio*.

The preceding directions, faithfully carried out, will, I firmly believe, bring every cold to its shortest, most agreeable termination. If pneumonia should develop, the only drug to be used internally is tincture of strophanthus under the tongue by means of hypodermic tablets.

"Stuff a cold and starve a fever" is good teaching, somewhat modified, even to-day. I would advise moderate eating and drinking for an ordinary cold; I advise liquid nourishment during the first forty-eight hours, in any event, if there is notable fever. If marked weakness supervenes, the best alcoholic stimulant, as brandy or whisky, with a small cupful of hot, well-made black coffee, or tea, is invaluable. As to frequency of repetition, it should be according to the patient and the symptoms.

BEVERLEY ROBINSON, M.D.

42 WEST THIRTY-SEVENTH STREET,
NEW YORK CITY.

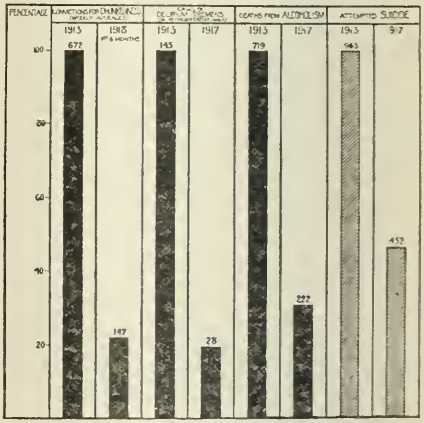
OUR LONDON LETTER.

(From Our Own Correspondent.)

TEMPERANCE ADVANCE IN ENGLAND AND WALES—THE STATISTICS OF BRITISH MEDICINE—THE PREGNANT MUNITION WORKER.

LONDON, August 28, 1918.

NEARLY two years ago the Central Control Board (Liquor Traffic), a government bureau, which came into existence to deal with the temperance question in all its aspects of maintaining manhood and womanhood efficiency throughout the country, appointed an advisory committee to consider the conditions affecting the physiological action of alcohol. The committee, whose personnel has already been stated in these columns, was extremely strongly constituted, comprising Sir George Newman, the principal medical officer to the Board of Education; Professor Cushny, professor of pharmacology at University College, London; Dr. H. Dale, principal biochemist to the Medical Research Committee; Dr. M. Greenwood, statistician to the Lister Institute; Professor McDougall, reader in mental philosophy at Oxford; Colonel Mott, pathologist to the London County Asylums; Professor Sherrington, professor of physiology at Oxford; and Dr. W. C. Sullivan, medical superintendent of the Rampton State Asylum for Criminal Lunatics. Such a body, with Lord D'Abernon as chairman, was particularly well adapted to report in every direction as to the effects on health and industrial efficiency produced by alcohol, and to plan out and direct any further investigations which might appear desirable. The first result of the committee's work was a review of the existing state of scientific knowledge regarding the action of alcohol on the human organism. The conclusions have been published representing "the unanimous judgment of the committee," which, of course, implies that to a certain extent the document was a compromise one; but it is none the less very valuable, defining the position of alcohol rather as a narcotic than as a food or stimulant, indicating the differences between its drug action and its poison action, while pointing out the factors which mainly contribute to the formation of the alcohol habit. The Central Control Board is now issuing in diagram form some useful little cards illustrating the



present condition of the country with regard to temperance, as compared with its condition before the war. The diagrams present extremely interesting pictures. The preceding diagram, which deals with the reform that has taken place in the use of alcohol by women, tells a dramatic story of the temperance advance in England. The present condition, compared with the pre-war condition, is little short of remarkable:

The figures for suicide, where the amelioration which has taken place can only be claimed as partially due to abstinence from alcohol are faintly shaded, the improvements due absolutely to moderation in drink being shown in black. With such evidence before them—and the figures for men are no less striking—it need hardly be said that the medical profession will support certain measures of restraint in the liquor traffic after the war.

The educational number of *The Lancet* contains an article which summarizes, with the necessary tables, the numerical position of the medical and dental professions in the United Kingdom, the information being given to show how far the shortage of medical students promises to embarrass the community in the future. The number of medical students now actually engaged on their studies is certainly very low, 7,600, but that is 1,500 in excess of the number two years ago. The following analysis of the students shows a remarkable rise in the proportion of female students as compared with a few years before the war; but it also shows that since the war began the proportion has not increased; in other words, the young women, like the young men, have found that the war offers opportunities for service of many sorts. I take the figures from a statement made by the president of the General Medical Council:

Percentage of Men and Women Students.

	Men.	Women.		Men.	Women.
First year	68	32	Fourth year ...	73	27
Second year ...	67	33	Fifth year.....	82	18
Third year	68	32			
			All years	71	29

The total number of names on the British Medical Register is now, according to *The Lancet*, 43,819, distributed as follows:

England and Wales, 23,175, being 54 per cent of the whole number.
Scotland, 13,918, being 32 per cent. of the whole number.
Ireland, 6,176, being 14 per cent. of the whole number.

The numbers added by registration, removed on evidence of death, and the totals remaining on the register on the last day of each of the last five years are shown in the following table:

Year.	Number Added by Registration.	Number Removed on Evidence of Death.	Number of Names on the Register on Dec. 31.	Increase on the Previous Year.
1913.....	1,168	746	41,940	501
1914.....	1,433	1,068	42,378	438
1915.....	1,526	800	43,225	847
1916.....	1,202	1,005	43,483	256
1917.....	1,134	831	43,819	338

The yearly additions in the last column do not agree precisely with the differences between the preceding columns, inasmuch as a certain number of names are removed from or replaced on the Register each year on formal grounds. It is noteworthy that during the last three years no name has been removed from the Register on account of the bearer ceasing to practice. So far the number of names on the Register has increased from year to year, but it is quite evident on referring to the numbers of medical students due to qualify in the years 1919-21 that this increase will not be kept up unless the mortality gets smaller, as a greater supply of medical men is obtained from abroad. There are 5500 dentists on the Register of the United Kingdom, the figure being a small rise on the total of last year. The war has produced no shortage here.

The greatest human interest of the present day is perhaps the increase of the race. The world war has shown the value of human life at the moment when circumstances are rendering human life the smallest counter in the vast game of world politics; but alike for the armies that are and for the civilization which is to come the question of population is of permanent importance. Therefore, all measures must be encouraged which tend to promote the greater well-being of the mother before and at the time of confinement, for these, coupled with infant welfare, form the most direct method of insuring the health of the coming generation. If the pregnant woman can remain in a more healthy condition than her ordinary domestic circumstances allow, be better fed during that time, as well as after her confinement, and can feel sure that the infant will be treated as a valuable charge by the State, the birth rate will go up and infant mortality will sink. A woman who is struggling for existence, and who is debarred from earning a good wage *because she is pregnant*, is discouraged instead of helped at a time when she should be given all the aid that is possible, because she herself is giving to the State the aid which it chiefly needs. It has long been held by hygienists, humanitarians and advanced supporters of the rights of women, that the pregnant woman should be encouraged, if possible, to abstain from work for at least one month before and three months after her confinement, so that she may both enter upon the ordeal in the best circumstances and not return to her work until she has completely recovered her normal state of health. Moreover, during the first three months after confinement the nursing of the infant is of paramount importance, and any routine work interferes with this function in every conceivable way.

With some such views as these in her head, Dr. Mary A. S. Deacon, medical officer to a shell-filling factory, read a paper at a recent Oxford Welfare Conference, on the employment of pregnant women in munition factories. It may be premised that the factory was in every way a well-planned, well-managed, and well-found establishment, presenting none of the gross evils of environment associated with many of the foul barracks in great trading centers. Dr. Deacon kept records during the nine months from the beginning of June, 1917, to the end of February of this year, with a view to finding out the effect of munition work on the pregnant employees. Of the total number of women workers engaged during the indicated period, 575 were married and 622 single, and the problem which Dr. Deacon set herself to consider was whether, when the women became pregnant it was better to dismiss them at once or to keep them at work until within a few weeks before confinement, and, without dogmatizing in her reply, she evidently came to the conclusion that for most women the arguments were in favor of their being kept on. Good feeling is in this way

promoted between the employers and the employed, if the workers feel that the management is not ready to penalize them for natural physical disabilities, where all the trouble falls upon the women while the benefits accrue to the State. Such good feeling produces actually better work among all the other women employees. They help. And should there be any work naturally falling to a pregnant woman where a strain is put upon the abdominal muscles, they not only help, they attempt to supersede the weaker sister, and the output of the factory in the long run does not suffer. If the worker continues as long as is safe at her work, she saves more money for the time during which she will be laid by, and can thus afford to take a longer rest after confinement, which implies full opportunities for the breast-feeding of the infant. There is another point which must be borne in mind: Miscarriages are actually fewer in a factory where the conditions of pregnancy are known at an early date, and the worker is not tempted to take drugs or use other means to promote a miscarriage for fear of losing her work. Dr. Deacon's interesting paper was supported by a summary of records showing that women who had worked in sympathetic conditions till shortly before their confinement had not suffered by so doing, and had produced healthy children. The message of her interesting paper is that, to dismiss a woman from a factory because she is pregnant is not only inhuman but thoroughly uneconomical. As a matter of fact, in most factories the work can be classified into light, medium, and heavy, and the pregnant woman can, as a rule, be put systematically into the less arduous class. Such transfer of labor implies cooperation on the part of the factory management which is not always forthcoming, and the sympathy of the other women workers which can always be expected. The education of factory managers is what is chiefly required, and here the opinion of medical men will have great weight. The factory managers are not callous—they are simply without the necessary knowledge of physiology and sociology to enable them to understand the health, temperament, and position of a pregnant woman.

OUR LETTER FROM PARIS.

(From Our Own Correspondent.)

EXCELLENT WORK OF PARIS AMBULANCE SECTION—REORGANIZING THE MAIL DELIVERY SYSTEM—CAN WAR MUTILATIONS BE INHERITED—INFLUENZA IN PARIS.

PARIS, August 13, 1918.

FEW are aware of the work performed by the American ambulance service in connection with the American Red Cross Military Hospitals. There are three sections, each composed of forty-five men and twenty ambulances, one camion, one camionette, and one motorcycle. The wounded from the front come usually at night and during the day those who can be removed are taken from hospitals in and about Paris to the trains, this part of the work being carried out in conjunction with the French. From the month of June up to date, about 8,000 wounded have been received by the ambulances in Paris, and for the year thus far about 20,000 have been received.

At one of the more important receiving stations the wounded on arrival are placed on the platform, whence ambulance men take them to the sorting room and lay the stretchers on racks. Then food and cigarettes are distributed by the French auxiliaries. A ticket is attached to each wounded man, indicating where he is to be taken. For instance, face and jaw wounds are dealt with at one hospital, leg wounds at another, gas victims at another, and so on. Then the men are wheeled to temporary sheds and placed in front of the ambulances according to numbers corresponding to their tickets. Here is where the American ambulance drivers come in. As there are about 150 hospitals as destination, the work can be imagined. One night, for instance, the ambulance made in all 350 trips, each trip meaning the transport of about ten wounded, so that approximately they carried 3,500 wounded to the various hospitals. Many of the wounded had been hit by machine-gun bullets. They displayed remarkable courage and fortitude. While the utmost care is shown for the wounded, the drivers have to rough it. I asked one driver had he lunched? "No," was the reply. Why? "Oh, I'll get something." When? "Oh, I will eat when I can." I asked others how much sleep they got. The reply was that they got sleep when they got a chance, between trains, and so on. Some of the drivers had not had their clothes off for several days. Self-sacrifice is the order of the day, and not a word of regret or grumbling.

A large number of badly wounded from the American front arrived in Paris on Thursday night and were distributed among the various hospitals, according to their wounds. This is the most important arrival of the kind. They came from Bouresches, from Veuilly, and from Belleau Wood. The men bore their sufferings like heroes and excited the admiration of all who saw them. Asked how the Americans stood the preliminary and other operations, the surgeon replied with pride: "Why, they bear their sufferings like Frenchmen. I cannot say more than that."

Much has been said about the delivery of letters among the troops or, to speak more correctly, the late or even non-delivery of letters. The American Red Cross is "up to the difficulty" in a manner worthy of imitation. In the Avenue Gabriel buildings, Lieut. George F. Miller is in charge of the Red Cross Postal Service. Mr. Miller knows his business. He has had twenty years' experience in New York City, where he was in charge, as a Federal employee, at the Grand Central Depot with 1,400 men under him. He handled about 400,000 letters a day. On retiring from the postal service Mr. Miller took up the position of assistant comptroller of the Bowery Savings Bank. With just two months work in Paris, Mr. Miller has changed the postal service of the American Red Cross in a remarkable degree, adopting New York methods in everything possible. While there are three offices in running order in this branch of Red Cross work, the office in the Avenue Gabriel seems to be the head office or center. The post office used to be conducted by women, many of them French, but none had any experience in post office work. Now there are forty-two employees.

composed of Americans, English, and some French. There are in the Avenue Gabriel offices five "guichets," including the departments of stamping, general information, inquiries, general delivery, cablegrams, and parcels service. Letters for the Red Cross workers, Y. M. C. A., K. of C., and the American Expeditionary Forces are all taken care of.

The American system of daily reports or lists has been adopted, showing where the various delivery vans go and when they return, with the names of the drivers and the mail clerk, whose signatures are affixed, so that the manager can see at a glance where each employee is and where each delivery van is at any time of the day. In addition to this is a list of the personnel showing who are present and who absent and why absent. Altogether the Red Cross postal service is in admirably good hands and the best results may be expected.

A great number of women who have married or will marry soldiers suffering from mutilations received in the war are asking: "Do my children run any risk of hereditary mutilation? . . . Will they be born physically perfect, or can they be born like father?" An answer to this question will obviate much uneasiness and mental suffering. There is abundance of evidence that certain characteristics of the parents can be transmitted to the offspring. It is a matter of everyday observation that children resemble their parents in facial appearance, stature, and build. The Bourbon nose and the Hapsburg lip have been transmitted by the males of the race for centuries despite their alliance with women of very varied descent. The tendency to obesity is very commonly inherited. As regards actual deformities and abnormalities, that common deformity of the face constituting hare lip is definitely transmissible, as are abnormalities of the blood-vascular system and the skeleton. As instances of the latter may be mentioned narrowing of the pulmonary artery and increase in the number of fingers and toes. That pronounced tendency to bleed which constitutes the disease of hemophilia is essentially hereditary.

If there is much evidence to show that such parental characteristics can be transmitted, what can be said of the possibility of transmitting war mutilations? Before answering this question let us look at the case of other acquired deformities not resulting from wounds or conservative war surgery. Is there any evidence that they can be transmitted? In the Chinese Empire it is customary so to manipulate the feet of the children that considerable deformity results. Nevertheless this deformity has to be produced in each generation afresh, for it is never transmitted. The same must be said of those mutilations which are carried out generation after generation by certain races from religious motives or from custom. They have to be repeated upon each individual all through the ages. As regards war mutilations, the answer is also in the negative—they cannot be transmitted. In those cases above which apparently favor the suggestion that the parents may transmit certain characteristics to their children, the reason is that the germ cell is primarily affected, and has, so to speak, ineffaceable characteristics stamped upon it. Such a condition cannot be brought about by mutilations of outlying parts of the body, and there is no evidence worth the name that the children of this generation will suffer from the fact that their male parents have shed their blood or sacrificed limbs in the cause of their country.

The epidemic of influenza which started in Spain and jumped to England has appeared among the German troops in Flanders and a few isolated cases have been seen among the wounded in the Paris hospitals coming from that front. This is all that can be said about influenza in Paris, and it is not possible to say whether the cases already reported, which are at present isolated, will be followed by a real epidemic. It is hardly probable that this will be the case. The 1889 epidemic began right away. It attained simultaneously a large number of Parisians. Then the initial centers of the malady became merged, and the epidemic assumed a general character. The present influenza does not appear to have created centers. The cases seem to have developed quite isolatedly. The evolution of the malady itself indicates the method of treatment. The attack comes to an end by the patient perspiring abundantly. As the best therapy is that which helps nature, the best treatment will be to produce perspiration. When the perspiration has finished the temperature drops and the patient enters into convalescence.

Through the generosity of Captain Mirault, on active service with the French army, the American Red Cross has been given free tenancy of the "Château Normand" at Beauvais, which is one of the most beautiful old landmarks of the district. The house contains more than twenty rooms, with a big garage and extensive grounds. As it is near the Red Cross hospital it is ideally situated for use as a headquarters building. Comforts and supplies are distributed from this base to the American army divisions, and sleeping accommodation and warm meals are given free from time to time to officers and men coming from or going into the trenches.

3. Toxic Nonexophthalmic Goiter.—Edward Hiram Reede defines toxic nonexophthalmic goiter as a neurosis of the craniosacral or parasympathetic branch of the vegetative nervous system, accompanied by perversions of metabolism and associated with a goiter more or less distinctive in pathology; whereas, the so-called exophthalmic goiter is a disturbance of the thoracicolumbar or sympathetic branch of the vegetative nervous system, associated with activity of the thyroid and suprarenal glands and a goiter with a distinct

pathology. The sympathetic system is an exploiter of energy, while the parasympathetic is a conservator of energy and depressor of action. Reede believes the influence of the thyroid obtains through its indirect effect through metabolic variations in the nerve tissue or through metabolites produced in the course of thyreogenic metabolism. Injection of the active principle of the thyroid into the blood stream elicits no effect for thirty hours, nor does this injection, as Levy has shown, have any immediate influence on the cardiac vagus nerves, which corresponds with the massive intoxication occurring on the second day after thyroidectomy. The parasympathetic and sympathetic nerves are theoretically in balance, but seldom so in practice. A sympatheticotonic child who develops an active goiter becomes more sympatheticotonic, and in the same way a vagotonic child becomes more vagotonic. The work of Kendall suggests that the sympathetic stimulation is due not only to the suprarenal, but also to a preurea compound produced by the active suprarenal in the course of protein metabolism, and that, therefore, thyroid activity in the absence of a simultaneous suprerenal cortex activity does not produce the usual so-called hyperthyroid symptoms, but a condition of depression. The pathological histology from the standpoint of the epithelium is that there is always a primary retention of colloid, with atrophy of epithelium and sometimes a regeneration. Grossly considered, goiter may be a colloid, an adenoma, a carcinoma, or an adenomatosis. In childhood primary enlargement of the thyroid occurs as a reaction to neighborhood infection, its later activity being due to other stimuli; it may also occur as part of a general infection. The enlargement of the gland does not determine its activity. Marine considers goiter to be due to an insufficient iodine ration and has instituted iodine medication in schools in a large community in the Great Lakes goiter district. The inciting stimuli to thyroid oversecretion are toxic, metabolic, and psychic. The symptoms are in part an appanage of the original stimulus and not essentially thyreogenic and in part a reflexion of diffuse metabolic disturbance, but in the main represent expressions of parasympathetic dysfunction. The simplest classification is the blood pressure grouping of Plummer into (1) constantly toxic high pressure; (2) constantly toxic low pressure; (3) inconstantly toxic low pressure, and (4) an intermediate group. This classification features the factor of vital moment in the prognosis, *i.e.*, cardiovascular degeneration, which, according to Krumbhaar, may be manifested by any type of cardiac irregularity. The occurrence of a thyreogenic cardiopathy from thyroid oversecretion without appreciable goiter is a physiological possibility. Symmers has identified idiopathic dilatation and hypertrophy of the heart as a thyrotoxic cardiopathy and associates with it a definite structural alteration in the gland, terming it a chronic interstitial and hyperplastic thyroiditis. This may have an interesting bearing on myocardial anomalies occurring in the course of the anxiety neuroses. The toxic high pressure goiter group may be divided into (1) a stage of vascular stimulation; (2) a stage of fixed vascular hypertension; (3) a stage of cardiovascular degeneration. From clinical evidence, Reede has reached the conclusion that the incipient exophthalmic always shows heightened sympathetic tone and that the later vagus symptoms represent an exhausted sympathetic and do not indicate a true vagotony in the sense of primary vagus tone. In cases not distinguished by an exophthalmos, Reede has noticed the frequent occurrence of nervousness of the spastic type associated with stimulation of the sympathetic which antedates the goiter and is increased by its appearance. He offers a tentative clinical classification, citing cases in its support, and points out that the toxic high pressure goiter never becomes exophthalmic, apparently because the capacity of the suprarenals is inadequate to stand the quantity production essential to that sympathetic superstimulation. The first stage—that of vascular stimulation—in the high pressure group is characterized by the presence of an active focus of infection in the body, the occurrence of a psychic repression of high potential, often sexual, and evidences of increased metabolism with psychomotor acceleration and heightened mental tension. The subjective feeling is one of strength rather than weakness and is accompanied by much restlessness. The second stage—that of fixed hypertension—is identical in symptoms with the condition to which Janeway gave the name of primary hypertensive cardiovascular disease with the added feature of a goiter. There is generally progressive infection and often psychic factors of irritative import. Mild vagotonic symptoms appear after periods of definitely prodigal energy expenditure. The third stage of cardiovascular degeneration is a picture of arteriosclerosis and myocarditis plus an asthenia, a pigmentation of the skin, and a slowing, both mental and motor, that suggests Addison's disease; a vascular nephritis adds an albuminuria. It has been suggested by Hoskins that the asthenia may be explained as due to overstimulation of the suprarenals leading to final atropy. The toxic low pressure group includes the great majority of cases of parasympathetic stimulation with goiter. The prerequisites to the study of goiter are: an adequate conception of the rôle played by the vegetative or autonomic nervous system and an intimate acquaintance with its functional expression; a familiarity with the physiological evolution of the normal individual from child to adult with the usual reactions in puberty, adolescence, pregnancy and the climacteric, and some knowledge of the goitrous individual's variants; an elementary study of personality as determined by the phylogenetic instincts termed cognitive, affective, and conative. The action of the vegetative nervous system is primarily autonomic, but this automatism is perverted through three agents, the hormones of the ductless glands, the actions of toxins, and the effect of psychic stimuli transmitted through the central nervous system, and often through the combined action of all three factors. It includes secretory processes of the digestive glands, as well as secretory action of the organs that separate the urine, the sweat, and the milk; the work of the heart and the distribution of the blood in the body through changes in the caliber of the vessels in the different parts; the work of the respiratory mechanism; the propulsion of food through the digestive canal, the emptying of the secretions from the digestive glands, the muscular activities of the ureters and bladder and of the system of genital ducts in both sexes; the state of nutrition of the muscles, the carbohydrate metabolism, the nitrogen metabolism, the heat regulation, the deposition of fat and the growth of bone. The relation of the thyroid to a psychoneurosis is probably threefold; it may sensitize latent tendencies, it furnishes a soil for luxuriant growth, or it may be an end product. Experimental evidence is constantly accumulating as to the important rôle played by the vegetative nerves. Porter and Newburgh observed that in dogs with pneumonia after section of the vagi the violent dyspnea is succeeded by quiet breathing. From a pharmacodynamic study of typhoid fever, Matsuo and Murakami conclude that in the majority of cases a state of vagotonia or one of sympatheticotonia exists, that the bradycardia is a vagotonic phenomenon, and that in their series all the deaths occurred in the sympatheticotonic cases—which may form a basis for prognosis. The inconstantly toxic low pressure group differs from the preceding group only in the history and in the less destructive effects of the intoxication. Intermittent nervous breakdowns are separated by periods of good health. There is not a high health threshold but specific infection or psychic traumata anticipate the several breakdowns. There is usually adenoma. In the intermediate group pressure is between 130 and 160, the arbitrary standard used by Plummer, which suggests probable terminal hypertension and vascular degeneration like the high pressure cases, but also luxuriantly exhibits the vagotony of the low pressure group. In treatment, the consideration in class one is the degree of vascular and myocardial damage present or imminent. As a rule, surgical interference is the surest way of blocking an intensive process. In the low pressure group the question is more as to the degree of ill health than actual duration of life. The following steps should be taken: (1) removal of focal infections; (2) relief of psychic irritation; (3) surgical intervention. Operation should consist of bilateral lobectomy. Vagotonic disorders may be relieved by local palliatives. Many cases of goiter in children can be prevented by prophy-

lactic treatment; Reede believes that the condition is largely the result of deciduous dental sepsis and is of the opinion that girls from five to twelve should be examined yearly and the cephalic extremity kept free from all infections. If a goiter is already present, the transit of the girl through puberty demands protection. Especial care should be taken to keep the body free from focal infection during pregnancy, and attention paid to the condition of the thyroid during adolescence, after child birth, and at the menopause, when the demands upon it are particularly heavy.

The Treatment of Wounds with Catgut Strands.—Neuhäuser states that besides the antiseptic treatment of wounds, modern surgery has discovered the necessity of filling in cavities resulting from deep seated tissue destruction. This neoformation of tissue can be greatly stimulated by foreign bodies, a fact which led the writer to use bundles of catgut strands, placed over the raw surfaces in order to provoke an exuberant growth of granulation tissue. For example, in a funnel-shaped wound the bundle of catgut will itself assume a funnel shape and when pushed into the wound cavity will line the walls. At the end of ten days the granulations are already growing in the direction of the catgut strands and a few days later a compact mass of granulation tissue will be found to fill the cavity. The writer advises leaving the first bundle of catgut in place for two weeks, if possible, without change of dressing, but should this be necessary the catgut can be removed without tearing away the granulations already formed. The results of this method of treatment are all the more marked the greater the vascular supply to the parts involved. Epidermization is also stimulated by this procedure and in this respect the writer has had good results in cases of varicose ulcer, torpid amputation stumps, chronic empyema and osteomyelitis.

The Treatment of Wounds of the Ureter During Laparotomy.—W. Weinreb offers a general survey of this question and reports a personal case. He gives the following reasons for preferring ligature of the injured ureter to nephrectomy. Ligature, followed or not by a nephrectomy later on, allows the fellow kidney to progressively assume the functions of the other organ, so that a nephrectomy done later on will in most probability be successful.

The Elimination of Bromine in Man After Digestion of Sodium Bromide.—W. Authenrieth, by the procedure of calcination of the urine, followed by the calorimetric test of bromine, has come to the following conclusions: Bromide given in a single dose or in two doses given near together is retained for quite a time in the organism. In subjects with normal kidneys the largest amounts of the bromine are eliminated during the first three days, after which the remainder is eliminated in decreasing amounts. On the thirty-fifth day the quantity eliminated represents only 72 per cent. of the bromine absorbed. The elimination during the first 24 hours was only 3.2 per cent. of the total amount ingested. In subjects with nephritis the elimination was three times less during the first ten days than in subjects with a normal urinary function. The influence of the exhibition of NaCl is merely an indirect one, in this sense that it does not influence the amount of bromine eliminated, but by producing thirst and, therefore, the ingestion of water, the resulting diuresis carries off the bromine more rapidly. At all events, the elimination is too irregular to allow one to establish an equilibrium between the doses ingested and the amounts eliminated. The writer has also been able to note that the bromine retained in the blood of a nephritic subject is dissolved in the serum and cannot be demonstrated in the corpuscles.

The Results Obtained by Systematic Provocation of Malaria.—W. Hoffmann recalls the importance of detecting soldiers afflicted with malaria, even in the latent form. It would seem to be a confirmed fact that a number of infections and epidemics of malaria are to be attributed to unrecognized instances of the disease, the subjects being the source of infection of mosquitos in a given region. The appearance of malaria in previously uninfected regions and coinciding with the end of winter is essentially attributable to this manner of contagion. The procedures of provocation and consequently those of diagnosis, enumerated by the writer, are as follows: Injection of sterilized milk, faradization of the splenic area, injection of tuberculin, typhoid vaccination and divers other vaccines. Besides, general irradiation with the ultraviolet rays may attain the same end, while adrenalin has been resorted to for the object of contracting the unstriped muscles of the spleen and ergotin and hypophysary products likewise possess a similar action. Hoffmann has employed the following procedure: A vapor bath at 55° C. for ten minutes followed by a bath at 20° C. for three minutes. On the following day these baths are repeated. Then he resorts to faradization of the splenic region until rubefaction has taken place and this is followed by muscular exercises with douching and cold compresses over the spleen. This very varied procedure has not given rise to any untoward effects on the health of the men submitted to it, while the results obtained have been directly utilized from the standpoint both of prophylaxis and treatment. Out of a total of 480 apparently cured convalescents, 9 per cent showed that they were still infected with the plasmodium. Of these forty-one cases four had the organism in the blood which could be detected in the hanging-drop preparations with clinical symptoms of distinct malarial paroxysms. The provocation of the disease had to be renewed in several instances before a positive result could be obtained and one patient, Hoffmann reports, did not react until the provocative procedure had been resorted to twelve times.

Expert Military Examination of Epileptics.—A. Schüller estimates at 28 per cent. the number of true cases of this affection sent to special hospital services for expert examination. The writer also recommends the formation of special hospitals for war epileptics following wounds of the head, infectious diseases and from uncertain factors.

Migration and Effects of Bacteria in the Central Nervous System.—Homen covers the work of the Pathological Institute of Helsingfors since the 90's of the past century. He discusses the various ways in which bacteria and their toxins reach the central nervous system, including the result of personal researches into injections into the sciatic and other peripheral nerves and the cord. The different toxins establish particular processes and set up special alterations, but these are also modified by outside influences. The bacteria show types of behavior and the various tissue elements show types of reaction. This is especially true of the glia cells, which in various toxi-infectious processes show remarkable ability to proliferate. The differences between local action and action at a distance having been touched on, the author sketches the rôle of the bacteria in both simple and mixed infection, including the mixture of anaerobes with aerobes. There is a local as well as a general predisposition to infection. The distinction between purulent and non-purulent toxi-infection receives considerable attention, as does also the peculiar position in pathology of the meningitides. In all of these study fields, the following should go hand in hand: Clinical study, antemortem pathology, postmortem changes and animal experiment, both from bacteriologic and pathologic viewpoints.

Wound Treatment Without Dressings: Open Air Treatment.—Langenskiöld refers to German labors in this field, especially those of Dosquet. The author has tested the principles and technique of the latter and reaches the same conclusion: to wit, that in both infected and purulent wounds the normal method is the open method, to be renounced only on special indications. Dosquet's method has been carried out in a small hospital in Berlin. The literature thus far is very small aside from Dosquet, but two men have reported on the method. The idea of the latter is by no means new, for it can be traced back to 1800. Initiated in Vienna by von Kern, it held a place in surgery, and Rose was able to show percentages under the open method which were far superior to those of Billroth. But Listerism sidetracked it for the time being, until the peculiar conditions of the present war led to its revival.

Affections of the Optic Chiasm.—Behse describes a case of affection of the chiasm due to empyema of the ethmoid and sphenoid cells. There were bitemporal right sided hemianopsia and left sided hemiamblyopia. The patient had contracted the infection in a cold, damp bedroom. He first complained of a chill and headache. Not until the lapse of five weeks did the eye troubles appear. After surgical intervention he improved somewhat, although there was a permanent defect in one visual field. An exacerbation a year later led to a second operation, which relieved a condition of diplopia, due evidently to paresis of the right motor oculi. Some of his previous improvement was subsequently lost and both visual fields are now defective. The prognosis in these cases is not good.

La Presse Médicale.

June 10, 1918.

Chloremic Edemas of Non-Nephritic Origin.—Labbé refers to cases of edema seen as complication or sequela of dysentery. In the first example the swelling extended upward as far as the thorax, involving scrotum and prepuce. The urine was scanty, but otherwise normal, heart normal. Upon a regimen poor in chlorides comprising theobromine the edema rapidly disappeared in the midst of profuse diuresis. The author believes that the condition arose because of hepatic insufficiency. The man was an alcoholic and heavy eater and showed slight icterus. The urine of the diuresis was rich in chlorides and there seemed to be no doubt of chlorine retention which could not have been due to renal lesion. The second patient, in addition to dysentery, showed marked anemia. In addition to ordinary anasarca, he presented ascites. He improved on the measures used on the first patient. The edema was succeeded by a dehydration, patient losing over 2 kilos daily for a considerable period. At a later period under diet he regained his weight and normal blood count.

Case of Late Tetanus.—Antoine relates the case of a soldier who was recovering from fracture of the thigh. The bones were united and the injuries of the soft parts cicatrized. There was complaint of insomnia and sweating, agitation and anxiety, and finally of rigidity in the affected limb. The incubation period was over eleven weeks. The picture of tetanus gradually appeared, but the course, while severe, was not malignant. The patient responded to treatment, although he had two relapses. He received, in addition to serum, injections of carbolic acid. He had received a prophylactic injection thirty hours after injury and it seems a fair inference that this injection had retarded the development of the disease. The carbolic acid was injected subcutaneously into the affected limb.

Tetanus Localized in a Limb.—Chauvin states that up to 1910 but twelve cases of this type were upon record. Since the outbreak of the war they have repeatedly occurred. The author alone controls six cases. In all of the post-bellum cases, as far as known, serum had been given as prophylactic, and one obtains the impression that it is the action of the serum which localizes the infection. At the same time we must believe that the immunization, while it saves life, is essentially incomplete.

Le Progrès Médical.

June 8, 1918.

Radioscopy of the Stomach After Normal Repast.—Ramond and Carrié refer to the great and continuous interest of this subject which is the order of the day. Even after meals the stomach casts no shadow on the screen, and the best means of obtaining the latter is the suspension of bismuth. The best formula is bismuth (subnitrate or subcarbonate) in half a pint of solution of gum arabic, aromatized with lemon essence. Another good vehicle consists of one pint of a decoction of tapioca or other starch mixed with milk. But these fluids do not, of course, give the true outline of the stomach in its active manifestations. The amount of fluid cannot fill the organ and its introduction does not provoke movements such as follow introduction of solid food. The bismuth also tends to deposit or sediment in the stomach and its presence in the empty organ often causes nausea. Hence the metal should be given with solid food. A bismuth meal best consists of a mince of meat (75 gm.), potato (150 gm.), butter (40 gm.), fat bacon (30 gm.), seasoned with a little parsley, garlic or chive, to which is added 40 gm. of bismuth subnitrate. This hash is eaten by patients with relish. It is not enough for an entire meal, so that the balance is made up of bread, eggs, red wine, coffee, etc., taken at pleasure. Eighteen healthy men were subjected to the same trial meal and examined with the screen in the standing posture. The organ consists of a superior cul de sac, the direction of which is almost vertical, a body which lies horizontally and a pyloric end directed slightly upward. The cul de sac lies wholly to the left of the spine, the pyloris wholly to the right, while the body crosses the spine. The position of the organ may be high, medium, or low. The cul de sac in each position is at about the same level, so that the descent affects the body and pylorus. The medium and low placed stomachs are, therefore, more voluminous and the stomach has a greater length. A medium level is the more commonly encountered, the pylorus corresponding to the navel. After the meal the fluid portion rises to the top, the air being at once expelled. The pylorus commences to function at once.

SECTIONS ON OBSTETRICS AND GYNECOLOGY.

Third Day—Thursday, May 23.

Nitrous Oxide in Labor.—Dr. RAYMOND C. COBURN of New York presented this communication. He said that while twilight sleep had had its day, he felt that it had done a great deal of good in waking people up to demand relief for the woman in travail. After drawing the distinction between analgesia and anesthesia, he said that nitrous oxide analgesia should be instituted as soon as the contractions produced a decided pain which was usually at the end of the first stage; the emphasis, however, should be put on the degree of pain rather than on the stage of labor as the guide for beginning the administration of the nitrous oxide. To administer the nitrous oxide a more or less complicated apparatus was required, yet it could be administered by a comparatively simple apparatus and a single cylinder. The patient should be instructed how to cooperate. Upon the first indication of the contraction, either announced by the patient or detected by palpating the abdomen, the mask should be quickly applied and the patient should take three deep rapid inhalations of the nitrous oxide. At the end of the third inhalation she should hold her breath as long as possible and "bear down." This usually furnished complete analgesia for a complete contraction. It was quite essential that the patient should hold her breath as long as possible. The bearing down not only augmented the expulsive effort but also increased the rapidity of the absorption of the nitrous oxide. The number of inhalations was important and should be regulated according to the requirements, no more being used than was necessary to produce analgesia. The nitrous oxide was discontinued during the interval between contractions. Two deep inhalations gave quite a deep analgesia with the average patient and four gave a marked analgesia. The writer discussed the different types of apparatus that might be used and said that different types of inhalers might be used. He preferred the face inhaler. It was possible after instruction for the patient to administer the nitrous oxide herself and this was a psychological aid as it directed the patient's mind to extraneous matters. Five to twenty per cent. of air or of oxygen might be admitted with the inhalation of nitrous oxide as a routine. The writer discussed the technique by which the amount of oxygen could be regulated. When the nitrous oxide was administered only after the uterus had begun to contract and then only for a few inhalations very little if any nitrous oxide reached the fetus, for the contracted muscle prevented it reaching the fetal circulation until the end of the contraction, and by that time most of the nitrous oxide had been eliminated as it left the blood stream about as rapidly as it entered. It was not advisable to allow the patient to become cyanosed. If the patient showed signs of cyanosis more air should be admitted or fewer inhalations should be given. If at first pains were severe but ineffectual and the analgesia did not work well a good sedative should be administered. When the head was passing over the perineum the analgesia should be continuous and deepened into anesthesia if there was danger of a tear. Nitrous oxide would not prevent the pain of a deep laceration. The use of chloroform should not follow nitrous oxide analgesia. He was much afraid of this sequence and reports from a hospital in New York where this sequence had been tried confirmed his fears. If a deeper anesthesia were required ether might be used; it acted about as quickly as chloroform when given after nitrous oxide and was to be preferred as an adjunct to nitrous oxide.

Dr. PAUL TOMPKINS HARPER of Albany said there were several points in the paper that were illuminating, but he must confess that he was not a competent critic as he had had but little experience with nitrous oxide analgesia, at the Brady Hospital. He believed that everything that was said was perfectly true. They had used nitrous oxide but had not employed the perfection of technique that Dr. Coburn had described. Perhaps the most striking illustration of its use was in a case of myocarditis acute in its working up. The operation was a therapeutic abortion at four months. The patient was a most undesirable surgical risk. After about fifteen or twenty minutes of nitrous oxide anesthesia, the percentage of oxygen furnished being about 20 per cent. when the preliminary operation was finished, it was observed that the heart action was better than at the beginning of the operation. It was interesting to watch the lighting up and reddening of the blood as oxygen was increased to give more stimulation and less anesthesia. He had used nitrous oxide anesthesia in perfectly normal patients for the sole reason of relieving pain and the only objection to it was the question of expense, but it seemed likely that the advantages it offered outweighed even its excessive cost. It was a great boon in cases of toxemia in which the heart and the liver were involved and in which it was a question of whether ether should be employed. In such cases it was practically a specific.

Dr. QUIGLEY of Rochester said he had used nitrous oxide in labor for two years. It was not applicable to ward work on account of the expense. Patients who had had it once asked for it if they were confined a second time and were perfectly willing to stand the cost. He always had it given by an anesthetist and did not think it was possible for the obstetrician to give it himself, not because he could not master the technique but because he would be occupied with the conduct of the second stage of labor. In his experience he had used it in only one case in which it was not entirely satisfactory.

Dr. ZINKE of Cincinnati complimented the author of the paper on his splendid presentation of the subject, and said that it was a paper that should be read by everybody. Personally he did not accept obstetrical cases any longer, but he was delighted by the manner in which this subject was treated by the younger men in the profession. Personally he had had no bad results from chloroform, but he thought that where prolonged analgesia was desirable the nitrous oxide would be preferable. The only objection was the expense and the complicated apparatus, the fact that one did not always have an expert to administer it, and that it could only be used in a hospital. It would probably have a more extended use when women were more disposed to go to the hospital for confinement.

The Underdeveloped Uterus.—Dr. CHARLES LYBRAND BONIFIELD of Cincinnati read this paper, in which he said that the development of the uterus might be arrested during uterine life, during early infancy, or at puberty. The rudimentary type of uterus was rare, was usually accompanied by absence of the vagina, and by rudimentary ovaries, and nothing could be done for it. The infantile type of uterus was more common than the rudimentary. It was usually associated with a cervix of small size and there was as a rule no menstruation. If menstruation did occur it was at long and irregular intervals. The pubescent uterus was quite common and varied in size from that of the infantile uterus to almost normal. Some of these uteri were sharply anteflexed and some were retroflexed and in all there was a tendency to cystic ovaries. Menstruation was late in becoming established and early in stopping, often beginning at about seventeen years of age and stopping at the age of forty. The women usually consulted a physician between the ages of nineteen and twenty-four years. The women who had this condition were of three types. The first type was the small frail woman who had just missed being a dwarf. The second type was practically normal in size but had never fully rounded out. The third type was the robust woman with a somewhat male build. These women did not become fecundated. They came with the history of certain conditions existing at puberty. They sometimes gave a history of a severe infection such as typhoid fever, scarlet fever, malaria, or chorea. Such a history was more frequently found in the second type of women. Dr. Robert T Morris had pointed out

that when nature tried to adapt herself to cultural standards, women more often showed arrested physical development than men, and that one seldom found a woman who was 100 per cent. feminine. In fact, there was a class of women who ought not to breed. The third type belonged to this class. The thyroid seemed to undergo enlargement at the time of puberty and this enlargement seemed to indicate an increased demand for its secretion; this furnished an indication for the administration of thyroid extract. In the small woman there seemed to be a deficiency of pituitary secretion. The symptom that usually brought the patient to the physician was dysmenorrhea. This was usually slight when menstruation began but became increasingly severe as time went on. This was because of the anteflexion and the narrowed cervical canal that dammed the secretions back and which finally produced an endometritis. Then just as a weak heart dilated and became hypertrophied so the uterus, with the blood supply interfered with, enlarged in the supravaginal portion and the infravaginal portion became shortened. This type was the most numerous and the least understood. It was the type in which the uterus approached most nearly to the normal development and the ovaries and uterus did not correspond in development. Sometimes one would find normal ovaries with a rudimentary uterus. As in most other conditions prophylaxis was better than treatment so was it in the condition under consideration. If the family physician could be convinced when menstruation did not begin at the usual time that something was wrong he might do much for the correction of the condition and he need not make a pelvic examination. Personally the writer had had little opportunity to treat these girls, as he was not in general practice and did not see them until in later years, but he believed these girls could be helped by medical and hygienic treatment, by attention to the intestinal tract, by diet, laxatives, attention to the teeth, tonsils, appendix, or any other source of focal infection. Thyroid, pituitary, and ovarian extracts should be judiciously administered. The only treatment that would help later in life was surgical in character. This consisted in dilatation, curettage, and packing with gauze. If the uterus, and particularly the cervix, was packed tightly with gauze the uterus would contract and frequently with sufficient force to expel the gauze. He allowed the gauze to remain in the uterus for five days, as the contractions were the best exercise to develop the uterus. For the medical treatment one might give thyroid for two or three weeks and then stop that and give ovarian extract for two or three weeks. In the more severe cases he had the patient come to his office the day before menstruation and gave her a hypodermic of corpus luteum, two ampules of the Parke Davis preparation. He also prescribed hot drinks and a hot sitz bath. If menstruation did not appear he let her go until the period came around again and then repeated the treatment. If the patient was excessively fat he reduced her by diet and exercise. In some cases matrimony gave relief; these women might abort a few times but later pregnancy would go to term.

Dr. James E. King of Buffalo said that of late years a study of the ductless glands had resulted in attributing many curious conditions to some abnormality in these glands. The interrelation of these glands was a very interesting subject and this feature Dr. Bonifield had brought out. The subject had not been given as much attention as it deserved. There was a type of girl who was fat and reached puberty without any sign of menstruation; she was certain to like sugar, did not like school, and led a vegetative life. She was finally brought to the physician because of amenorrhea and he said she had an infantile uterus and the case was dismissed. As a matter of fact this was a case of hypopituitarism. The pituitary gland was one of the most important glands in the development of the sexual organs and particularly in women, and when the pituitary gland was disturbed there would be certain manifestations which could be found if they were sought for. If the pituitary gland did not secrete properly there would be a disturbance in metabolism and the first thing to be observed would be an inability to assimilate sugar. If one gave a normal individual one hundred grams of sugar it would appear in the urine in a certain time, but if there was a diminished pituitary secretion that person could take 200 or 250 grams and there would be no reaction in the patient's urine, and these patients with pituitary perversions would surprise one by the large amounts of sugar that they could take without having it appear in the urine. These facts gave one an indication for treatment. He had tried pituitary extract and had had no definite results, but he felt confident that the remedy for these cases would some day be found.

Dr. A. W. Marquis of Norwich said that in her work she examined a great many girls and found that the girls with menstrual disorders could be divided almost into two classes. In the first class were those in whom the whole body was underdeveloped; they were not well rounded, as Dr. Bonifield had pointed out, and these girls had as a rule enlarged thyroids. They menstruated once in two weeks though the flow might be scant, and they sought relief from the annoyance occasioned by this frequency of menstruation. She had found that if thyroid and a few hypodermics of pituitary extract were administered it made the interval between menstrual periods longer. Then there was a class of girls who went overtime and in whom the thyroid was underdeveloped. They also required thyroid treatment and ovarian extract. It was quite remarkable the number of girls that had overdeveloped thyroids. In the routine examination of 145 girls she had found 16 with overdeveloped thyroids and they almost invariably had menstrual disorders.

The Management of Breech Presentations.—Dr. Paul Tompkins Harper of Albany presented this communication, in which he directed attention to certain clinical aspects in breech presentations and to the broader consideration of the physiological mechanism of labor which should be the basis of the conduct of these cases in which expectancy was the policy determined upon. There was a mechanism of labor peculiar to breech presentations and in connection with this there were three features to be emphasized. (1) The complete dilatation of the service, (2) the engagement, descent, and birth of the arms, flexed; (3) the engagement of the aftercoming head, its descent in the oblique diameter, and birth, after traversing the curve of the pelvic canal, by flexion. These points were mentioned particularly because to the extent that they were not manifested or were nullified by actual interference it could be shown that accidents and complications increased both in frequency and intensity. The familiar complications were: (1) dry labor; (2) retraction, used synonymously with impaction; (3) extended arms; (4) intrauterine asphyxiation from delay in delivery of the aftercoming head, and (5) perineal laceration. Dry labor was an unavoidable accident in most cases. Retraction was a grave complication, but preventable to the extent that premature rupture of the membrane predisposed to it, and ample opportunity for the prophylactic and active treatment of it was offered. Extended arms and extended head were complications that were not primary, that was, they were preventable to the degree to which the operator controlled expulsion and advance. Perineal laceration was avoidable in vertex presentations and due almost or wholly to the manner of advance and delivery of the aftercoming head. Expectancy was the course decided upon in the absence of absolute or even relative pelvic deformity. Granted the case was one in which delivery was not imperative the conduct of the second stage might be summarized as follows: In response to the propulsive uterine contractions, the frequency of which might be increased by persistent gentle massage of the fundus and the intensity of which should be augmented by persistent downward pressure on the fundus exerted by the hand of the assistant, the breech gradually distended the perineum and was born. The feet might be lifted out of the vulvovaginal opening which sometimes retarded their advance. Anterior rotation commonly was incomplete and the buttocks as frequently were born in or approximately in an oblique diameter. Subsequent expulsive efforts were to be awaited and the temptation to exert traction resisted. Since the arms were to descend in an oblique diameter, no attempt should be made to rotate the back to the front. The danger of pressure on the cord at this time was slight; however, it should be anticipated and the fetal heart frequently auscultated. With the next contraction the navel was commonly born. At this point it

was imperative that at each contraction fundal pressure be increased. As advance was accomplished, the child's body was raised and two fingers inserted beneath it were directed upward to meet and pull downward first the elbow of the flexed posterior and then of the anterior arm. It was at this time that firm traction was too frequently employed. Following expuisive efforts resulting in the birth of the shoulders the uterus was frequently inactive and tractile force to deliver the aftercoming head would have to be correspondingly increased. Such force applied about the child's head, face, and trunk entailed the danger of injury to nerve trunks as well as that of extensive perineal lacerations due to rapid advance and delivery of the head. The child's body was raised obliquely over the maternal abdomen and the final expulsion effort of the uterus awaited. The body was raised obliquely so that the anatomical relation between it and the aftercoming head which was to advance in an oblique or transverse diameter of the inlet might be preserved. It was placed over the maternal abdomen that it might be expended upon the head which was to undergo progressive flexion and to follow the curve of the pelvic cavity. Firm, intermittent, suprapubic pressure was the most available and satisfactory force to supplement the feeble uterine expulsive force at this point. When spontaneous or artificial expulsive efforts were insufficient to produce advance the head might be brought into the midpelvis by means of the forceps. Moderate traction might be exerted by the finger in the child's mouth. As to the administration of anesthesia, a little might be used late in the first stage, but in the second stage it should be eliminated as giving it lessened uterine contractions and delayed the delivery.

JOINT SESSION OF THE SECTION ON MEDICINE AND SURGERY.

Wednesday, May 22.

DR. THOMAS F. LAURIE OF SYRACUSE IN THE CHAIR.

Symposium on Goiter.

The Function of the Thyroid Gland.—Dr. HENRY S. PLUMMER of Rochester, Minn., presented this subject (by invitation). This gland, he said was of the highest interest to the clinician, the surgeon, the neurologist, as well as to the embryologist and the histologist. The normal thyroid was doing quantitatively half as much work as it did in exophthalmic goiter, and one third more than the highest grade of myxedema in which there was no thyroid. A certain metabolic rate could continue without the thyroid, but at a very low ebb. Exact measurements of metabolism were made by grouping cases according to the estimated minute volume of blood from the heart. The data on which conclusions were based had not as yet been published. The basal metabolic rates of some 2,000 cases had been studied and classified. In regard to energy, the energy production of a gas engine, for instance, varied as the rate of excitation of potential energy in the cylinder; that was also true of energy transformation in animal cells. All available energy became transformed into motion or heat on excitation. The thyroid hormone (isolated as a pure crystalline compound) was a catalytic agent controlling a quantum of potential energy for transformation to heat or motion, on excitation of the cell. At rest, 14 hours after eating, the dynamic equilibrium was approached. The rate of energy production, 12 hours after eating, in the horizontal position, was 39 calories per square meter, of the body surface. The normal individual varied little from this. When there was little or no variation from this, there was no functional thyroid disturbance. The rate of energy production varied with the amount of the hormone in the cells; the hormone remaining constant, the energy rate varied with excitation. Change of amount of hormone in the tissues caused change in the basal rate of metabolism. These conclusions were corroborated by the medical and surgical aspects of the disease. Administration of the hormone caused the thyroid gland to pick up the hormone. This had been studied in typical myxedema cases, where the characteristic syndrome was that of low energy output. In one-third of the cases of hyperthyroidism, there was excitation of the gland by adenoma of the thyroid. If the condition were removed, the metabolism very shortly dropped to normal.

Newer Methods in the Diagnosis of Thyroid Disorders, Clinical and Pathological.—Dr. EMIL GOETSCH of Baltimore sent this paper (read in his absence by Dr. C. Webb of Clifton Springs). Work in Dr. Halsted's clinic was undertaken and 216 goiter cases were studied. Of these 10 were colloid goiters; 50 were exophthalmic goiters; 150 were adenomata; 6 were unclassified. The work was divided into 2 phases: (1) histological and clinical; (2) as to the local and constitutional hypersensitiveness to adrenalin. In the colloid gland there was accumulation of colloid and symptoms of hyperthyroidism; later, with increase of thyroid epithelium a hypothyroidism occurred. In exophthalmic goiter, there was diffuse pathological change in the thyroid gland. There was epithelial hyperplasia. In the adenomata there was great variation in the type of clinical picture presented. At first there was increased irritation by pressure, and later atrophy. There were no fixed rules of development in these cases. The clinician could not outline the pathological picture, and the pathologist could not realize the clinical symptoms from the appearance of the gland. The presence of mitachondria in all of the ductless glands showed that these were definite histological elements in the cytoplasm of the cell. These were found in enormous numbers in exophthalmic goiter and in adenomata of the thyroid. In the colloid gland there were almost none. The normal gland was between these extremes. The adenomata tended to degenerate into hemorrhagic cysts and at this stage symptoms of hyperthyroidism disappeared. An increased sensitiveness to adrenalin was a symptom of hyperthyroidism. The thyroid hormone evidently possessed a sensitizing action to adrenalin upon the cells of the sympathetic nervous system. The reaction was characteristic. There was rise in blood pressure, tremor, throbbing and vasomotor changes. Nervousness was greatly increased after adrenalin according to the degree of the toxicity present.

Medical Treatment.—Dr. HERMAN C. GORDINIER of Troy presented this phase of the subject. A brilliant therapeutic effect having been obtained by the use of thyroid in goiter, the profession were looking for a cure in Graves' disease. No such treatment had been forthcoming. Patients, thoroughly discouraged, sought relief from treatment by daring surgeons. Surgeons were apt to do too much and physicians too little. The disease was protean in character, often ending in cardiac failure, but many cases improved under medical treatment. In medical treatment of Graves' disease, there must be absolute cooperation of the patient with the physician. The disease must be recognized in the early, atypical forms. Any focal or systemic infection, underlying the thyroid condition, should be sought for. A general toxemia from acute infectious disease might be the causative factor. Treatment was by rest, both physical and mental, for a long time. Fresh air, sunshine, a dry climate with moderate elevation were all indicated, and the treatment should be similar to that for early tuberculosis. An intelligent, optimistic nurse, with experience with nervous patients would have a saving effect. It was better to carry out treatment in a hospital or sanatorium, than in the home. The time of treatment would be decided by the severity of the toxemia and of the cardiac symptoms. It was necessary to recognize the cases early. With irritable tachycardia a delicate fine tremor was an early constant symptom. Falling out of the hair was often seen. A careful white blood cell count should be made. Leucopenia was often found. Feeding of these patients was an important point. They were generally thin. The calcium content of the food should be increased. Plenty of pure soft water was essential and perfect elimination should be aimed at. Drugs in these cases were uncertain in their action, but neutral hydrobromide of quinine, used over a long period of time had been found to have very good effect. Digitalis seemed to be of use only in cardiac insufficiency. There was no agreement of opinion as to the value of various gland products. One worker gave corpus luteum with gratifying results. It was doubtful, however, whether the improvement was not due more to rest and general hygienic methods. Some workers reported good results from radiation. The nerv-

ousness decreased, the gland subsided, and general improvement was noted. The effect could be accurately measured by thoroughly experienced workers and if necessary, operation could be performed later. Most early cases would be found amenable to rest and hygienic measures, and those that showed no improvement should be placed in the hands of a competent surgeon. Success in treatment depended on careful individualism.

Surgical Treatment.—Dr. CHARLES W. WEBB of Clifton Springs presented this paper. The surgical treatment depended greatly upon the correct diagnosis. The work of Dr. Goetsch had evidently done much to properly classify these conditions. Three types could be named: (1) colloid; (2) adenomata; (3) exophthalmic types. The first did not require surgical treatment. The second had toxic effects upon the heart and central nervous system. Operation was necessary in these cases. The third should be operated upon before reaching the dangerous stage, which made the surgeon dread the proposition.

Dr. S. STERN of New York said that it would be difficult to overestimate the importance of the papers presented this afternoon. The thyroid was coming into its own. The tremendous importance of its functional effect on metabolism was being recognized. His experience in the treatment of exophthalmic goiter had been by means of radiotherapy. In the last 17 years he had treated about 250 cases of exophthalmic goiter. The cases of cystic goiter were ruled out as they did not respond to radiotherapy. They were referred to the surgeon. In regard to radio effects,—small doses were stimulating; large doses inhibitory in effect. Very large doses caused atrophy. The question was entirely one of technique. It had to be very carefully regulated to accomplish just the result required on the cells of the gland. The treatment was getting easier year by year as knowledge of radiation increased. The point would be reached when no cases of Graves' disease or exophthalmic goiter would be operated upon. With medical treatment and radiation, relief could be given in all cases. The first symptom to yield to radiation was nervousness and insomnia; the next tachycardia (although it was difficult to get the exact pulse rate as the patient was usually excited by coming to the physician's office). The pulse rate should be taken at home. The size of the thyroid would be reduced in the majority of cases. In some it did not diminish entirely. The exophthalmos was the most difficult symptom to change and the last to disappear, but within the past two years a technique by means of defiltered rays seemed to accomplish more results in regard to this symptom. The last ten weeks had given better results and in 4 cases this symptom had entirely disappeared.

Dr. G. T. MATLACK of Wilkes-Barre, Pa., who discussed this paper by invitation, said that Dr. Plummer's paper was wonderful. He would like to hear more details as to the mitochondria from Dr. Webb. The work of Kocher and C. H. Mayo would show that surgery was a safe procedure, with proper technique. The question arose, what types of goiter should be operated upon. A type of goiter occurring before puberty, in which later marked hyperthyroidism occurred, required operation. It was also necessary in those cases of adenoma of the gland where pressure and destruction of gland tissue interfered with physical and mental development. This beginning cretinism was relieved by operation. The exophthalmic thyrotoxic type required definite surgical treatment. The results obtained would depend upon the method of procedure. One should not operate in the height of an attack, at a stage where the patient was getting worse, as in an attack of diarrhea. The thyrotoxic goiter was not improved by ligation. This type very rarely showed eye symptoms. One point should be emphasized—one should keep track of patients operated on for goiter. Without proper supervision they might get worse than before and the cases were then incurable.

Dr. N. W. SOBLE of Rochester, N. Y., said that he would like to ask if Dr. Plummer used adrenalin as a therapeutic aid in hypothyroidism. Frequently women at the menopause showed symptoms of hypothyroidism. Obesity, loss of strength, loss of sleep, constipation were noted. They did not respond to ordinary thyroid therapy. If adrenalin would increase hyperthyroidism, would it have therapeutic effect on hypothyroidism? Dr. Gordinier had mentioned pigmentation. This had always been considered leucodermia or obstruction of the coloring matter. If anything could be done, it would be interesting, as this condition was an annoying one, especially to women. He did not like to add any more "signs" to Graves' disease, but he thought that a rarification of the outer eyebrow was often seen in hyperthyroidism. There was also a dysuria, without cystitis, due to hyperplasia of the urethra.

Dr. D. H. MURRAY of Syracuse said that Dr. Plummer had mentioned chlorophyll. Chlorophyll released its energy only in the presence of another energy. Was this the case with the thyroid hormone? The testimony of Dr. Gordinier had an important bearing on these cases. Dr. Murray said he was operating much less than formerly on exophthalmic goiter. One of the other speakers had mentioned the difficulty of disposing of the symptom of exophthalmos, even when getting good results from radiation. This was due to spasm of the muscle through the hormone. The relation of this hormone to the arrangement of the ions on either side of the impermeable cell membrane should be considered. A difference in potential occurred because of arrangement of the electrolytes. Did the hormone increase impermeability by increasing osmotic tension? If so the activity of the entire cellular system was increased in response to the action of the hormone.

Dr. T. L. DEAVOR of Syracuse said that the papers were so deep it was difficult to discuss them. Emphasis should be placed on the rest cure. The question was, whether one could not continue that too long, so that while relieving the thyroid, one was causing an effect on the heart muscle. The surgical treatment could, with advantage, be added to the rest cure in properly selected cases. It would seem that extreme elimination was necessary, but just what that meant to metabolism, it was hard to say. Something in the intestinal tract evidently increased the toxicity of the thyroid. In operating on cystic goiter, one should not stop at removal of the cyst. The remaining thyroid tissue should be reduced, leaving the posterior aspect, near the parathyroid. The excessive action of the sudoriforous glands should be encouraged, and a great deal of fluid should be given. No line of treatment was the last word. All lines had their place and the combined efforts of the surgeon, the physician, and the radiologist were necessary to combat this difficult condition.

Dr. MARY DUNNING ROSE of New York asked why preference was given to fish, chicken, and lamb, in the diet of these cases, instead of a good juicy beefsteak. Was this because of the action of the putrefactive proteins in the intestinal tract? The protein content of beefsteak was 2.6 per cent. and much less than that of chicken.

Dr. G. E. BEALBY of Albany said that this meeting should prove of value to patients with hyperthyroidism. He believed there was no dispute as to the value of surgical treatment of goiter when the symptoms were produced by pressure on the gland. The results obtained by surgical technique in properly selected cases were far better than 50 per cent., they came nearer to 100 per cent. of cures. Dr. Goetsch's paper was valuable as a means of basal diagnosis. In regard to the white blood cell count—cases of hyperthyroidism had a very pronounced lymphocytosis, as high as 38 per cent., when the total increase in leucocytes was 8,000. This was a valuable diagnostic sign in the mild cases without exophthalmos, which were difficult of diagnosis. The surgeon should get the cases before complications arose. He had a case treated medically 8 years. That was too long.

Dr. H. S. PLUMMER said that in these cases more blood flowed out from the left heart; this was indicated by high blood pressure. There was loss of weight even when more food was taken. These symptoms should be diagnostic. Signs should be forgotten and men should get down to fundamentals. 90 per cent of myxedemas never got goiter at all. Hyperplastic thyroid was so rare as to be a curiosity. Exophthalmic goiter was a distinct entity associated with hypertrophy of the thyroid. Adenomata were a distinct disease. The profession had not learned about them yet. An adenoma was an adventitious new growth causing increased metabolism by heavy stimulation of the thyroid. When

removed the hyperthyroidism stopped. As to the white cell count, the lymphocytosis was also present in all other cases that might be confused with Graves' disease. Its diagnostic value was nil. As to adrenalin it would increase an already increased blood pressure. In regard to the sympathetic and vagotonic disturbances, 60 per cent. of the cases would get well if left alone. Half of the cases sent to the clinics never had hyperthyroidism. Nobody ever had 70 per cent. get well from medical treatment. Before the days of antitoxin 50 per cent. of diphtheria cases got well, but that was no argument against antitoxin. The hyperthyroidism was simply an increased metabolic rate. That must be brought down and the high calorie burning would stop.

Dr. C. W. Webb of Clifton Springs said that the adrenal test had been used with patients showing hyperthyroidism, and that the effect was always an increase of symptoms. No data was available as to any clinical effect of adrenalin in the hypothyroidism cases.

Perineal Prostatectomy.—Dr. Parker Syms of New York presented a short report on this operation, illustrated with moving pictures of the points in surgical technique. The advantages of this procedure over the suprapubic operation lay in the fact that it was very quickly performed, the prostate could be brought out of the wound and was in full sight during excision. The bladder was not opened at all, the prostate being reached through the incision in the perineum. The mortality was about half that of the suprapubic route. About ten minutes was required for the operation, and the patient was usually able to walk about within a week. There was no dripping of urine as in the suprapubic operation, the internal sphincter and external sphincter being absolutely intact. The drainage tube could be removed within 24 hours and the patient then had perfect bladder control. In selected cases a two stage operation was necessary. The perineal route then offered advantages. The incision could be made under cocaine and drainage instituted. Later the prostate could be removed.

Dr. E. M. Watson of Buffalo said that this was an interesting and graphic description. Looking at the pictures, one would think that the prostate fell out into one's hands. This was not so. He had seen Hugh Young have great difficulty in enucleating a fibrous prostate. The perineal or the suprapubic route was a matter of individual choice. The first perineal operations were usually not successful as the average surgeon did not know much about the perineum. In cases where a man was familiar with the technique the mortality was only about 3 per cent. In any cases where there were lesions of the heart, lungs, or kidneys, the perineal prostatectomy should be the method of choice. Multiple perineal scars would counterindicate this form of operation. In 24 out of 25 cases the internal sphincter remained intact in the perineal operation. It was better surgery to get the internal sphincter as nearly normal as possible. There might be questions connected with fertilization. The ejaculatory ducts might open into the bladder.

Dr. T. F. Laurie of Syracuse said that the proper diagnosis of these cases was important before choosing the route for operation.

Dr. Parker Syms said that he had only touched on work of Dr. Goetsch had evidently done much to prop the technique; he had not covered the subject of indications.

SECTION ON EYE, EAR, NOSE AND THROAT.

Thursday, May 23.

Dr. A. J. Bedell of Albany in the Chair.

Malingering from the Standpoint of the Eye.—Dr. Ellice M. Alger of New York made this presentation. The question of malingering had hitherto attracted attention in its medicolegal aspect, in regard to accident insurance and industrial injuries compensation. At the present time, on account of compulsory military service, a great many problems arose with regard to this question. Among the most difficult of these were questions relating to the eye. Eye symptoms were most easy to simulate, difficult to detect, and loss or deficiency of sight made an emotional appeal to the sympathies of a jury. In the army certain arbitrary standpoints had been adopted, certain definite defects of vision would disqualify a man. In the examinations for the draft, however, the lines were more difficult to draw. Often a man was accepted by the draft board and put to the expense of giving up his occupation and going to camp only to find upon re-examination he had defects of vision which should have been discovered at home and which unfitted him for class A service. In some cases young and enthusiastic men tried to memorize the test charts, so as to pass the standard, and officers had been known to let one candidate stand by while others were examined, so that he had a chance to get acquainted with the tests. On the whole there was very little occular malingering at the present time. This was different a year or two ago when some were pro-German in sympathy, some anti-English, some merely pacifists. Now the social pressure was all the other way, even among foreign citizens, and more were anxious to get through in spite of the tests, than to escape duty. As a rule a certain degree of vision without glasses was sufficient to pass the candidate, and ordinary examination would prove this, but if exemption were claimed on the ground of occular lesions, the services of an ophthalmologist were needed. This advisory board had more work than any other. Competent ophthalmologists were few and occular malingering was difficult to detect. Most important of all considerations was the mental attitude of the recruit. One at once became conscious of the underlying antagonism of the malingerer. He must be put rapidly through unanticipated tests. He very often failed on some elementary point and the more intelligent man was easier to catch than the stupid man who would not fence. It was well to let the man suppose that he was going to be rejected anyway and that the tests were mere forms. This put him off his guard. Very often macular defects were found with perfectly good central vision. The recruit often complained of vision that was not good enough for the firing line. It was important to give just value to the amount of vision, 20/100 being sufficient. The amount of myopia encountered was enormous and most myopes were found to be wearing too strong glasses. This defect would be improved by hygiene and camp life and should not preclude acceptance of the recruit. In testing the recruit one should ask about the occupation, and what the man supposed was the matter with the eyes. The malingerer was generally ready with a long story. His attention should be directed to a distance so that he would relax physiologically, and the patient should then be watched rather than the test card. The examiner should assume a credulous and friendly attitude and not appear to think that the man was malingering. In testing it was well to block out the good eye with strong glasses and in doubtful cases to make several tests at different distances. The honest man read promptly as far as he could, but the malingerer read slowly and with exaggerated difficulty. Often the mirror test was effective, the mirror increasing the distance. The recruit did not know this and read as well in the mirror as without. A recruit would generally admit good vision in one eye. To test the vision the diploscope was the simplest method. In this device things on the left were seen with the right eye, and vice versa, so that the man did not know really which eye he was using and the possibilities of deceiving the recruit with this instrument were many. The results of catching these men were, however, negligible. They would not fight in any case, while robbing the dead and finishing off the wounded were not accomplishments well thought of among American fighting men. The important point, however, was that many good fighting men were kept out on some technicality. Haig was color blind, but it did no harm for a general to "see red." Roosevelt had only one good eye, but no one thought him less efficient for thinking the war was less than 3,000 miles off.

Dr. W. M. Dunning of New York said that more than 400 cases had come up for examination of the eyes. Malingerers were relatively few. More men were trying to get in in spite of their eyes and were appealing against rejection. Even one man with a glass eye wanted to get into the army. He said if he

could not fight he could cook. The Advisory Board passed him back to the Local Board. Very many Hebrews were examined. The Hebrew was racially a myope. Every one with 20/30 vision should be accepted for limited service. Thousands of these men were giving satisfactory service to their employers without glasses; they could do the same for Uncle Sam. Dr. Alger had mentioned the use of midriatics, and perhaps of miotics. Dr. Dunning said he had had great temptation to make use of the latter. He had seen men learn the test cards and then go to the recruiting station and get accepted. He hoped they would soon be ready to fight.

Dr. VIRDENS of New York City asked what one was to do with the class of malingerer who pretended to be very desirous of entering the army, although one was conscious that he was anxious to evade the draft. These men were malingerers of the most dangerous type.

Dr. A. C. SNELL of Rochester, N. Y., said the psychological aspect was of first importance. He thought the method of using the test cards from the top down was useless. He often began at the bottom line, working up that way and 90 per cent. of men read the 20/20 line without mistake. Another method was the psychological one, that was running them off their feet, so to speak. The tests were put at arm's length and Harmon's apparatus for inverted tests was used. This was a question of cross vision. The man who claimed he was blind in the right eye was really reading with it. If this test was used rapidly, changing the distance frequently, the men got so mixed up that in a few minutes the examiner could get at the real facts.

Dr. A. E. DAVIS of New York said he would like to ask if the fields of vision were considered in these tests. One man came to him, accompanied by his lawyer. He was evidently posted on eye tests and he claimed to have only 10/200 vision, which would exempt him from the 2d class. He seemed to know his cues in all the tests, but finally he was put into a better light and the field test was made. He was not prepared for this. There was no sign of retinitis pigmentosa. He was told he was accepted for the draft. He said, "I don't know about that field test." Dr. Davis replied that that was exactly why it was made. The man was called for the draft.

Dr. SNELL of Rochester said he was able to catch a man on that very test, by proving that he really was looking with what he claimed was the blind eye.

Dr. A. J. BEDELL of Albany said that one man, the local optician, came to him. He claimed he had 5/200 vision. The lenses were good 150 with 50/90. The man was accepted, but he appealed.

Dr. E. M. ALGER in closing said that those malingerers apparently anxious to serve often went to the navy first. The navy had a much higher standard and they were often rejected. They expected that this would get them by the local board. The psychological attitude of the recruit was as important as the ophthalmological. The testing of the fields as a rule took too long, but occasionally there was found a hemianopsia due to some neurological condition. He had known a young man with a glass eye very anxious to get into the service. He believed he got in, but very likely not into the first line.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO BOARD OF MEDICAL EXAMINERS.

Denver, April 2, 1918.

(*Continued from page 486.*)

TOXICOLOGY.

1. Give symptoms of acetanilid poisoning.
2. Describe chronic lead poisoning.
3. What are the symptoms of arsenic poisoning?
4. Give symptoms of poisoning by cyanide of potassium.
5. Describe laudanum poisoning.
6. Name an acid and an alkaloid poison. Give symptoms.
7. Name chemical antidotes for corrosive sublimate, carbolic acid and tartar emetic.
8. Give examples of (*a*) irritant, (*b*) narcotic, and (*c*) narcotico-irritant poisons.
9. Name five vegetable poisons and give antidote for one.
10. Give symptoms of strychnine poisoning.

PATHOLOGY.

1. Give a description of adenocarcinoma under the microscope.
2. Describe *B. diphtheriæ*.
3. Exclusive of changes in the intestine what is the morbid anatomy of typhoid fever?
4. What conditions result from disease of the pituitary body?
5. Name some of the common fluids used for hardening tissues preparatory to section, with the strength ordinarily used.
6. Describe the phenomenon known as inflammation.
7. Give the morbid anatomy of acute endocarditis.
8. Describe the morbid anatomy of acute lobar pneumonia.
9. Discuss the cause of death from burns.
10. Discuss anaphylaxis.

SYMPTOMATOLOGY.

1. Discuss cholelithiasis.
2. Discuss ileus (intestinal obstruction).
3. Discuss parenchymatous nephritis.
4. Discuss erysipelas.
5. Discuss the prophylaxis and sanitary measures in caring for tuberculous patients.
6. Discuss mitral insufficiency.
7. Discuss chlorosis.
8. Discuss pertussis.
9. Discuss tetanus.
10. Discuss typhus fever.
11. Discuss sunstroke. How handled?

Answer any ten questions.

ANSWERS.

TOXICOLOGY.

1. *Symptoms of acetanilid poisoning:* Chilliness, cold sweat; nausea; pulse is soft, slow, and feeble; respirations slow and shallow.

2. The most *common sources of chronic lead poisoning* are the following: "The contamination of drinking water from lead pipes. Contamination of articles of food or drugs by contact with leaden vessels, or from being enclosed in tinfoil containing an excess of lead. Drinking beer, cider, etc., which has been drawn through leaden pipes or allowed to stand in pewter vessels. The ingestion or constant handling of lead or its compounds, as the acetate, nitrate, carbonate (white lead—painter's colic), Goulard's extract, etc. The use of hair dyes containing lead."

Symptoms: Anemia, emaciation, depression, pain round the umbilicus, hard and retracted abdomen, constipation or clay colored evacuations, diminished urine, fetid breath, blue line on gums, wristdrop, numbness of hand, paralysis, vertigo.

3. In *poisoning by arsenic: Symptoms:* "In acute cases the symptoms usually begin in from twenty to forty-five minutes. Nausea and faintness. Violent, burning pain in the stomach, which becomes more and more intense, and increases on pressure. Persisting and distressing vomiting of matters, sometimes brown or gray, or streaked with blood, or green (Paris green). Purging. More or less severe cramps in the lower extremities."

In *chronic cases:* "Inflammation of the conjunctivæ, with intolerance of light. Irritation of the skin, accompanied by an eruption (eczema arsenicale). Local paralyses. Great weakness and emaciation. Exfoliation of the cuticle and falling out of the hair."—(From Witthaus' *Essentials of Chemistry.*)

4. *Symptoms of poisoning by cyanide of potassium:* Lips and mouth are corroded, burning pain in throat and stomach, face pale and bloated, vertigo, insensibil-

ity, convulsions of a tetanic character, quick pulse, slow and stertorous respiration.

5. The *symptoms of poisoning by laudanum* are as follows: "At first there is usually a period of excitation, marked by restlessness, great physical activity, loquacity, and hallucinations. The patient then becomes weary, dull, and drowsy; he yields to the desire for sleep, from which at first he may be roused. The lips are livid, the face pale, the pupils contracted, and the surface bathed in perspiration. The condition of somnolence rapidly passes into narcosis. The patient cannot be roused, and lies motionless and senseless, with completely relaxed muscles. The pulse, at first full and strong, becomes feeble, slow, irregular, and easily compressible; the respiration slow, shallow, stertorous, and accompanied by mucous râles. The patient rapidly becomes comatose, and, in fatal cases, dies in from forty-five minutes to fifty-six hours, usually in from twelve to eighteen hours. In cases of recovery after the stage of narcosis the pulse and respiration gradually return to the normal, and the condition of coma passes into one of deep sleep, lasting twenty-four to thirty-six hours."

6. An *acid poison:* Hydrocyanic acid. An *alkaloid poison:* Aconite.

Hydrocyanic acid poisoning. Symptoms: "Its action is always rapid. Relatively small doses cause an immediate sense of constriction of the throat, followed in one to two minutes by sense of pressure in the head, vertigo, confusion of intellect, and loss of muscular power. The pulse is quick, the respiration slow and stertorous. Tetanic convulsions and involuntary discharges of urine and feces occur, followed by paralysis. Death follows in from two hours to two days from asphyxia. When large doses are taken no subjective symptoms are observed. The patient loses consciousness in less than one minute. There is a short convulsive seizure, usually accompanied by evacuation of feces, after which the patient lies perfectly still, with no sign of life, save an almost imperceptible pulse and infrequent spasmodic respiratory efforts, in which inspiration is short and expiration protracted. Death follows in from five to twenty minutes."—(Witthaus' *Essentials of Chemistry and Toxicology.)* Death is due to paralysis of the respiratory center and of the motor ganglia of the heart.

The symptoms of poisoning by aconite usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat. Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

7. *Chemical antidotes.* For *corrosive sublimate,* white of egg; for *carbolic acid,* sodium sulphate; for *tartar emetic,* tannic acid.

8. *Irritant poisons:* Nitric acid, sulphuric acid, hydrochloric acid, ammonia, caustic potash, potassium chlorate, phosphorus, iodine, chlorine, arsenic, antimony, mercury, oxalic acid.

Narcotic poisons: Opium, chloroform, ether, chloral.

Narcotico-irritant poisons: Alcohol, belladonna, and most alkaloids.

9. *Five vegetable poisons:* Belladonna, aconite, strychnine, tobacco, and elaterium.

10. The *symptoms of poisoning by strychnine* are "a sense of suffocation, thirst, tetanic spasms, usually opisthotonos, sometimes emprosthotonos, occasionally vomiting, contraction of the pupils during the spasms, and death, either by asphyxia during a paroxysm, or by exhaustion during a remission. The symptoms appear in from a few minutes to an hour after taking the poison, usually in less than twenty minutes; and death in from five minutes to six hours, usually within two hours."

PATHOLOGY.

1. *Adenocarcinoma* "is characterized by irregular or tubular cavities, paved with one or more layers of cylindric cells, and separated by a stroma which may be fibrous, embryonal, or mucous. In structure it occupies an intermediate position between the simple adenoma and true cancer. The cylindric cells are similar to those which cover certain mucous or glandular cavities, and are always implanted perpendicularly to the wall. The epithelial elements are similar to those of the mucous membrane from which they grow, but differ microscopically from the normal mucous membrane in the absence of a basement membrane (membrana propria). The slower the growth, the more typical the gland formation; in rapid growths and recurrences the cells are small and the lumina imperfect. The growths are soft, and often of a gelatinous consistence. On section they present a soft, watery appearance. The most common forms of degenerative changes are mucoid and colloid." (Coplin's *Pathology.*)

2. The *characteristics of the bacillus of diphtheria:* The bacilli are from 2 to 6 microns in length and from 0.2 to 1.0 micron in breadth, are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile, and aerobic; they are noted for their pleomorphism; they do not stain uniformly well by Gram's method and very beautifully with Loeffler's alkaline-methylene blue; they grow well on blood serum, slowly on gelatin, and with difficulty on potato.

3. *Exclusive of the changes in the intestine, the morbid anatomy of typhoid fever* is as follows: The mesenteric glands may undergo the same changes as the Peyer's patches, but more often become swollen, red, and tender only, or break down into cheesy masses. Other organs—Spleen and liver are enlarged and softened; heart is soft, fatty, and flabby and may show granular degeneration. The voluntary muscles undergo granular degeneration; in fact, similar changes to those found after death from high temperature. The kidneys are congested.

4. *Diseases of the pituitary body* may result in: (1) *Hyperpituitarism,* analogous to Graves's disease—as in hypophyseal tumors or hyperplasia—is an overfunctioning, perhaps due to chromophile activity. In early life, before the epiphyses ossify, gigantism results; if later, acromegaly. Emaciation, vascular degeneration, calcium retention, thyroid activity (stimulated by the anterior lobe) or adrenal stimulation (from posterior lobe) and lowering of the assimilation limit of carbohydrates may be observed. (2) *Hypopituitarism* or deficient internal secretion is analogous to myxedema; when it operates in early life, it induces dwarfism or infantilism, obesity, hypoplastic sexual organs and secondary sexual characters (Fröhlich's type), diabetes insipidus and great tolerance of carbohydrates; deficient secretion in later life induces reversive sexual infantilism; often there are dry skin, subnormal temperature and pulse, and drowsiness. (3) *Dyspituitarism* combines the above types, to some degree, just as symptoms of Graves's disease and myxedema may occur simultaneously or successively. (From Edwards' *Practice of Medicine.*)

5. HARDENING FLUIDS. *Alcohol,* from 80 to 95, or 97 per cent. *Formalin,* 10 per cent. *Müller's fluid. Orth's fluid. Osmic acid,* 1 per cent. *Corrosive sublimate,* 5 per cent. Zenker's fluid.

6. The phenomena of inflammation are dilatation of the arterioles, capillaries, and small veins. At first the blood current is quickened, then retardation occurs, and may progress to stasis and thrombosis. During this time exudation of plasma and white corpuscles from the small veins, and perhaps the capillaries, is going on. The fate of the white cell may be either to break up and set free prothrombin, or to act as food for connective tissue cells, or to act as a phagocyte and be transformed into a pus corpuscle. Red corpuscles may be exuded and broken up, setting free their coloring matter. The prothrombin of the white cells unites with the calcium chloride of the plasma and forms thrombin, or fibrin ferment, which acts upon the fibrinogen of plasma to form fibrin.

The tissues are thus invaded with numbers of leucocytes. In bacterial inflammation a varying portion of the tissues is killed by the toxins produced, and is either replaced by a mass of small round cells, or liquefied into pus. In the latter case it is surrounded by a

ring of small round cells. The connective tissue cells absorb the leucocytes, and new vessels are formed, thus constituting repair. In nonbacterial inflammation, exudation may separate layers of cells to a large extent and form blebs. In chronic inflammation the formation of new fibrous tissue is the chief part of the process.—(From *Aids to Surgery.*)

7. ACUTE ENDOCARDITIS. *Morbid anatomy:* In the simple form there will be found a cloudiness, followed by edematous thickening of the valvular endocardium; superficial erosions, and the formation of small granulations; deposits of layers of fibrin and corpuscles from the blood, the whole process resulting in the formation of small warty vegetations. These vegetations are most marked at a slight distance from the free borders of the valves—*i.e.* those parts which come into opposition during closure. In course of time they are transformed into fibrous tissue. According to Poynton and Paine the infective organisms are conveyed to the base of the valves by the capillaries, and thence pass to the subendothelial tissues by the minute nutrient channels in the valvular substance; others hold that the organisms are derived from the blood circulating over the surface of the valves. In the malignant form the initial changes are similar, but there are some important differences, inasmuch as ulcerations may completely replace the vegetations. The differences are: (1) The vegetations when present are larger and fungating. (2) The underlying tissues are necrotic and show loss of substance and round-celled infiltration. (3) They contain masses of micrococci, while in simple endocarditis the organisms are scanty. The two forms cannot be distinguished by the organisms producing them; either simple or malignant endocarditis may arise from a pyogenic infection. (4) When the vegetations become detached they form *septic* emboli, giving rise to metastatic abscesses. (5) The ulcerative process causes great destruction of the valves, and may even lead to perforation of the curtains. (6) The subsequent or permanent changes in the valves, if the patient survives, are much more marked. (7) If the vegetation touches the mural endocardium as it flaps to and fro, the part touched becomes affected by contact.

As regards the side of the heart most affected—*Congenital* endocarditis attacks the right side of the heart (but note that many congenital cardiac lesions are due not to endocarditis, but to developmental faults); simple endocarditis attacks the left only; the *malignant* attacks *both sides*, though the *left* is much more implicated than the right side.

The vegetations are upon that side of the valve opposed to the blood-stream—viz., at the aortic valve the vegetations project into the ventricle, at the mitral valve into the auricle.

As in pericarditis, the myocardium almost always shares in the inflammatory affection.—(Wheeler and Jack's *Practice of Medicine.*)

8. ACUTE LOBAR PNEUMONIA. "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aërated. The lung still floats in water. *Second stage or red hepatization.*—The part involved is solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation, which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Modern enlargement of the spleen is very common."—(Wheeler and Jack's *Practice of Medicine.*)

9. *Burns.*—"Much discussion has taken place regarding the explanation of the rapidly fatal issue in extensive superficial burns. On post-mortem examination the lesions found in these cases are: (1) general hyperemia of all the organs of the abdominal, thoracic, and cerebrospinal cavities; (2) marked leucocytosis, with destruction of red corpuscles, setting free hemoglobin which lodges in the epithelial cells of the tubules of the kidneys; (3) minute thrombi and extravasations throughout the tissues of the body; (4) degeneration of the ganglion cells of the solar plexus; (5) edema and degeneration of the lymphoid tissue throughout the body; (6) cloudy swelling of the liver and kidneys, and softening and enlargement of the spleen. Bardeen suggests that these morbid phenomena correspond so closely to those met with where the presence of a toxin is known to produce them, that in all probability death is similarly due to the action of some poison, the source and nature of which are as yet unknown."—(Thomson and Miles' *Manual of Surgery.*)

10. *Anaphylaxis.*—"By anaphylaxis is meant the following train of phenomena: When a foreign proteid is introduced by subcutaneous, intraperitoneal, intravenous, or subdural injection (or in some cases by feeding) into the animal body, after a time there will appear a specific hypersusceptibility of the animal for this proteid. After a definite interval, a second injection of the same substance, harmless in itself, will produce violent symptoms of illness and often rapid death in an animal so prepared. The phenomena are not limited to any given class of proteids, but are manifest in the case of animal, vegetable, and bacterial proteids, and within certain limits are specific."—(Hiss and Zinsser's *Bacteriology.*)

SYMPTOMATOLOGY.

1. CHOLELITHIASIS.—*Etiology:* Sedentary habits, catarrh of stomach and duodenum, microorganisms (*Bacillus coli communis*), obstructions to outflow of bile. *Symptoms:* "While the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, sex, history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces."—(*Pocket Cyclopedia*) and see SURGERY, *Question* 6.

2. *Ileus,* or *acute intestinal obstruction,* gives the following symptoms: "Sudden severe pain referred to the umbilicus comes on, perhaps, after an effort. Shock, evidenced by a weak pulse, a cold, clammy skin, and a subnormal temperature, accompanies the pain. The pain, intermittent at first, becomes continuous. Vomiting is persistent, and soon becomes fecal smelling. The patient becomes exhausted by the vomiting and inability to take food. The abdomen becomes distended, and if the obstruction is not relieved, perforative peritonitis follows, so that the patient dies in about seven to ten days from the onset. Constipation is usually absolute, though the lower bowel may empty itself at first."—(*Aids to Surgery*) and see SURGERY, *Question* 2.

3. *Acute Parenchymatous Nephritis* is an acute inflammation of the epithelium of the uriniferous tubules, characterized by fever, scanty, high-colored, or smoky urine, dropsy, with more or less constant nervous phenomena, the result of acute uremia. *Causes:* Cold and exposure, scarlatina, diphtheria, malaria, and other infectious diseases, traumatism to the back, pregnancy,

and the persistent use of irritants, such as turpentine, cantharides, phosphorus, ginger, etc., are the most common causes. It may also be associated with certain skin diseases, extensive burns of the skin, and simple follicular tonsilitis. The affection is most frequent in childhood. *Symptoms:* In mild cases, slowly developing dropsy with anemia, shortness of breath or dyspnea, and weakness are the only symptoms, the diagnosis being confirmed by the results of urinary examination. Usually, however, it begins suddenly with nausea, violent and persistent vomiting, fever, and dull pain over the kidneys, following the course of the ureters. There is a frequent desire to urinate, and diarrhea, harsh and dry skin, and a quick, tense, and full pulse are present. Dropsy soon appears, beginning first in the eyelids and face, but later becoming generalized. Anemia and weakness are marked particularly in post-scarlatinal cases. Uremic symptoms may develop at any time during the attack. The affection lasts from one to four weeks. The *urine* is of high specific gravity, 1025 to 1030, scanty, smoky (like beef washings) in color, due to the presence of blood. Albumin is present in large quantities, and the microscope reveals hyaline, blood, granular, and epithelial casts of the uriniferous tubules, blood corpuscles, uric acid, urates, oxalate crystals, and epithelium. The total amount of urea eliminated during the twenty-four hours is lessened from one-fourth to one-half. The amount of phosphates and chlorides is also lessened.—(From Hughes' *Practice of Medicine.*)

Chronic Parenchymatous Nephritis is a chronic inflammation of the cortical tubular structure of the kidneys; characterized by albuminous urine, dropsy, and increasing anemia, with attacks of acute uremia. *Causes:* It rarely follows an acute attack; in the majority of cases it is subacute or chronic from the onset. It is a disease of young adults, especially males, and is seldom observed after forty years of age. Habitual exposure to cold and wet, malaria, syphilis, alcoholic excesses, chronic mercurialism, lead-poisoning, opium habit, protracted suppuration, phthisis, hepatic disorders, pregnancy, and some undetermined nervous condition are the principal causes. *Symptoms:* The onset of the disease is gradual and insidious, being marked by a period of ill-health, anemia, digestive disturbances, weakness, puffiness under the eyes, most noticeable in the morning, dyspnea, cardiac palpitation, etc. Vomiting, without apparent cause, headache, vertigo, defective vision, and more or less generalized dropsy are also symptoms. Transient blindness is not uncommon in the early stages, but late in its course permanent loss of vision may occur due to retinal disease. Hypertrophy of the heart, with high arterial tension and accentuation of the aortic second sound are common accompaniments. Bronchial catarrh, with edema of the larynx, may also develop. Anemia is pronounced on account of the large loss of albumin and gastrointestinal disorders, and neuralgic pains are common. Uremic asthma and other manifestations of uremia may present themselves at any time. Irritability of the bladder is a very constant symptom, occurring very early in the course of the disease. The *urine* is scanty, high-colored, albuminous, and under the microscope shows hyaline and granular tube-casts, granular epithelium, and if fatty degeneration occurs, fatty tube-casts and oil globules. The increase above the normal amount of the urine, as the disease progresses, must not be forgotten when the specific gravity is low, 1.010-1.015, and the quantity of albumin is increased. The normal constituents of the urine, and particularly urea are diminished. In the hemorrhagic form, blood is present in the urine.—(From Hughes' *Practice of Medicine.*)

4. *Erysipelas* is caused by the streptococcus erysipelatis, which enters through a wound or abrasion. The skin and subcutaneous connective tissue are inflamed, and the lymphatic vessels are also involved; there is little or no pus formation, but leucocytosis is present, and the streptococci are found in and around the lymphatic channels. Round cell infiltration is common. The disease spreads by the lymphatics, and possibly also by direct continuity. Symptoms are chill; high fever; red, swollen mass, with clearly defined edges, itching, burning, and having a tendency to spread. Prognosis is good except in infants and puerperal women.

5. "The preventive measures which may be taken to reduce tuberculosis may be summarized as follows: (1) The compulsory notification of phthisis. (2) The removal of those conditions of domicile and of occupation which are known to promote the incidence of the disease, including the regulation of certain dusty trades. (3) The diffusion of knowledge (by medical men, leaflets, etc.) regarding the nature and modes of spread of the disease, and the precautions which should be taken in order to prevent its extension. (4) The testing of sputum and other suspected discharges, and of milk, meat, etc., supposed to be tuberculous—reports to be furnished free of charge. (5) Local authorities to undertake, without charge, the disinfection of houses recently occupied by phthisical persons. (6) The establishment of sanatoria and isolation accommodation for the cure of phthisical patients, and the isolation of those who are a distinct source of danger to fellow lodgers or workers. (7) The enforcement of measures against spitting in public conveyances and in places of public resort. (8) The efficient sanitary supervision of dairy farms, dairies, and milkshops. The periodical veterinary inspection and testing (by tuberculin) of milch cows, and the slaughter of tuberculous animals. The prohibition of the sale of milk of cows affected with tuberculosis. (9) The proper inspection of meat in public abattoirs, and the adoption of due precautions for the control of imported meat and milk."—(Parkes' *Practical Hygiene.*)

Hygienic precautions to be taken in treating a case of tuberculosis: "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spitcups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge baths of lukewarm alcohol and water."—(Thompson's *Practical Medicine.*)

6. *Insufficiency of the mitral valves* soon leads to cardiac hypertrophy, in order to compensate for the diminished amount of blood sent onward by the ventricular systole. This condition causes quickened and strong pulse with some shortness of breath on severe exertion. When compensation ruptures, it is manifested by precordial distress, cough, dyspnea, feeble, soft, rapid, irregular pulse, pulmonary congestion, edema of the limbs, ascites, general cyanosis, hepatic congestion, and scanty and albuminous urine; all of which symptoms may present themselves in varying degrees. When extreme, and compensation is not again brought about, death is the result. *Inspection* shows displacement of the apex beat downward and to the left. In children and youths, bulging of the precordium and increased cardiac impulse are present. In emaciated individuals, an auricular impulse may be observed to the left of the pulmonic area in the second interspace. *Palpation* serves to confirm inspection. The displaced cardiac impulse is forcible and diffused in the early stage; as compensation fails, the impulse becomes feeble or absent. *Percussion* shows an increase in the area of cardiac dullness transversely and vertically. *Auscultation* reveals a systolic or blowing murmur, heard best in the mitral area and transmitted to the apex, left axilla, and under the angle of the scapula. It may occur with, or take the place of the first sound of the heart, the second sound being markedly accentuated, particularly in the pulmonic area.—(Hughes' *Practice of Medicine.*)

7. *Chlorosis* is a form of anemia in which there is an excessive reduction of hemoglobin over that of the reduction of red blood-corpuscles. It generally occurs in females under the age of 20. Faulty hygiene, im-

proper food, overwork, constipation, tight lacing, and mental anxiety are etiologic factors. Defective development of the circulatory system and of the organs of reproduction often accompanies the disease. The heart is often in a condition of hypertrophy with dilatation.

The examination of the blood shows a decrease in the amount of hemoglobin, and the presence of microcytes, poikilocytes, and a few nucleated blood-corpuscles. There is no leukocytosis, and the number of red blood-cells is but slightly reduced. The skin is tinged yellowish green. Palpitation and breathlessness are common symptoms. The pulse is soft, but of good volume, and a systolic murmur is often heard near the base of the heart, and a peculiar hum over the right jugular vein. Hysteric and nervous manifestations are common. Gastric ulcer, phthisis, amenorrhea, and exophthalmic goiter may complicate chlorosis. The diagnosis is made by the examination of the blood. Under proper treatment the patient should recover.—(*Pocket Cyclopedia.*)

8. *Pertussis, or whooping cough* is an infectious disease characterized by a convulsive paroxysmal cough, consisting of a number of forcible expirations, followed by a series of deep, loud, sonorous inspirations (the whoop), repeated several times during each paroxysm, and associated with catarrh of the bronchial tubes. The disease is contagious and is due to an unknown microörganism associated with the sputum and mucous discharges. It is a disease of childhood, fully one-half of the cases occur during the first two years of life. Adults may be affected. One attack usually secures immunity. The *catarrhal stage* originates in an ordinary naso-laryngobronchial catarrh, with a loose cough. There is frequently a leukocytosis (chiefly of lymphocytes). Duration, one or two weeks. In the *spasmodic stage* the cough becomes *paroxysmal*, consisting of a succession of short, rapid, expiratory efforts, the face becoming red, the eyes swollen and protruding, the body bending forward, and when these expiratory efforts have exhausted the breath, they are followed by a deep, loud, crowing inspiration—the whoop: each paroxysm being composed of several such spells, the last one followed by the expectoration of a small amount of tough, viscid mucus. The attacks of cough may be so severe as to cause vomiting, and if the vomiting occurs shortly after food has been taken, the nutrition of the patient will suffer. Profuse epistaxis is not infrequent. Duration, about four weeks. In the *terminal stage* the paroxysms recur at longer intervals, are of shorter duration and less intensity, the catarrhal symptoms being more marked, the expectoration freer. Duration, one or two weeks, often followed by the "cough of habit."—(Hughes' *Practice of Medicine.*)

9. *Tetanus* is an infective disease of wounds due to *bacillus tetani.* Predisposing causes are occupations where a person is in contact with earth, going barefoot, carelessness when exposed to rusty nails, dirty implements, etc. Tetanus generally begins with malaise, then in 5 to 15 days after infection the muscles of the neck and of mastication contract firmly, the muscles of the trunk follow, and last of all the respiratory muscles. The spasm is never entirely relaxed, yet the least stimulus such as a noise or draught causes violent tonic contraction. Rapid pulse and dysphagia are present. Consciousness is unimpaired.

10. *Typhus fever* is an acute, infectious, and epidemic fever; highly contagious, and characterized by sudden invasion, profound depression of the vital powers, sickening odor, and a peculiar maculated and petechial eruption, favorable cases terminating by crisis about the fourteenth day. There are no characteristic lesions. It is due to a special organism, the *bacillus typhi exanthematici;* it is probably carried by bed-bugs and body lice. After an incubation period varying from a few hours to two weeks (generally about twelve days) the disease makes its appearance suddenly with a chill, followed by pains in the head, back, and limbs, and fever, the temperature reaching 105° or 106°F. within a few days. A severe angina is frequently the first symptom. The high temperature is maintained for about two weeks when it falls by crisis. The pulse is at first frequent and bounding, but soon becomes small, weak and rapid. The patient protrudes his tongue with difficulty, and often is unable to project it beyond his teeth. Prostration is extreme and is manifested by muscular feebleness, vertigo, tremor, and subsultus. On the third to the fifth day a coarse, red, diffused, measly eruption makes its appearance which rapidly becomes petechial or hemorrhagic. Associated with this is diffuse mottling of the skin which involves the entire body, excepting the face. The face has a uniform deep dusky flush and the skin appears glazed. The conjunctivæ are injected and the pupils are contracted. As the disease progresses there is cutaneous hyperesthesia, muscular soreness, and tenderness over the tibia. Headache is severe and often followed by delirium. Constipation is the rule.—(Hughes' *Practice of Medicine.*)

11. *Sunstroke.*—This condition occurs after exposure to the sun's rays. Premonitory symptoms consisting of headache, dizziness, nausea, and malaise are sometimes present, but not rarely there is sudden coma with high fever (105° to 110° F. or more), flushed face, dry skin, rapid pulse, and stertorous breathing. Muscular twitchings and epileptiform convulsions are not uncommon. Death may occur within a few hours or the temperature may fall, the coma disappear and recovery gradually ensue. Chronic meningitis, persistent headache, impairment of memory, and extreme sensitiveness to high temperature are frequent sequelæ. The mortality is probably not less than 40 per cent. *Treatment.*—The patient should be placed in a bath of ice-water and rubbed with ice. Ice-water enemas may also be employed. The intravenous or subcutaneous injection of salt solution has proved beneficial in some cases. Venesection (10 to 20 ounces) is said to be very effective in asphyxiated subjects.—(Stevens' *Practice of Medicine.*

(*To be concluded.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION †	
Alabama*	S. W. Welch, Montgomery	Montgomery	Jan. 14
Arizona*	A. B. Williams, 219 Goodrich Building, Phoenix	Phoenix	Oct. 1
Arkansas	T. J. Stont, Brickley	Little Rock	Nov. 12
California	C. B. Pinkham, Sacramento	Sacramento	Nov. 21
Colorado	David A. Strickler, Empire Building, Denver	Deover	Oct. 8
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Nov 12
Delaware	J. H. Wilson, Dover	Wilmington	Dec.
Dist. of Col'bia	E. P. Copeland, Washington	Washigton	Oct. 8
Florida*	W. M. Rowlett, Tampa	Jacksonville	
Georgia	C. J. Colon, Marietta	Atlanta	Oct. 8
Idaho*	Ray H. Fisher, Righy	Boise	Oct. 1
Illinois	F. C. Dodds, Springfield	Chicago	Sept.
Indiana	W. T. Gott, Crawfordsville	Indiannpolis	Jan. 14
Iowa	G. H. Sumner, Des Moines	Des Moines	
Kansas	H. A. Dykes, Lebanon	Topeka	Oct. 8
Kentucky	J. N. McCormack, Bowling Green	Louisville	
Louisiana	E. W. Mahler, New Orleans	New Orleans	
Maine	F. W. Searle, Portland	Portland	Nov. 12
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec.
Massachusetts*	W. P. Bowers, 1 Beacon St. Boston	Boston	Oct. 8
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Lansing	Oct. 8
Minnesota	T. McDavitt, St. Paul	Minneapolis	Oct. 1
Mississippi	J. D. Gilleylen, Jackson	Jackson	
Missouri	G. H. Jones, Jefferson City	Kansas City	Sept. 30
Montana*	S. A. Cooney, Helena	Helena	Oct. 1
Nebraska	J. J. Hompes, Lincoln	Lincoln	
Nevada	S. L. Lee, Carson City	Carson City	Nov. 4

THE MODERN TREATMENT OF GALLSTONE DISEASE AS AFFECTED AND CONTROLLED BY DUODENAL INTUBATION.*

BY JOHN C. HEMMETER, M.D., Ph.D., Sc.D., LL.D.,

BALTIMORE, MD.

FROM THE MEDICAL DEPARTMENT, UNIVERSITY OF MARYLAND.

Relative Frequency of Gallstones.—There must be great variations in the relative frequency of the occurrence of gallstones among different nations, and these variations depend upon the method used in ascertaining their existence, whether by simple clinical investigation, by operation, or by autopsy. One need only look over the alphabetical index of the *Journal of the American Medical Association* or that of the MEDICAL RECORD to be astonished at the large number of contributions to this subject, and also at the varying figures given concerning the frequent occurrence of this disease. Barker, in his splendid new work on the "Clinical Diagnosis of Internal Diseases," states that the percentage of human beings found to have gallstones at autopsy is five to ten. This may serve as an American estimate. Scheel, in *Ugeskrift for Laeger*, November 30, 1911, gives 15 per cent., based on 2,753 autopsies. Pel, in his "Krankheiten der Leber und der Gallenwege," page 312, quotes Halk as finding gallstones in 29 per cent. of all autopsies, and he himself, in his observations on the autopsies on old women performed in Amsterdam, found 20 per cent. of cases of gallstones in cases which had given no symptoms during lifetime. It should be added that Halk's material was composed of individuals over fifty years of age. In the article by Quincke and Hoppe-Seyler in "Nothnagel's Specielle Pathologie n. Therapie," the relative frequency of the finding of gallstones by twelve European pathologists varies from 2.4 per cent. to 29 per cent. The largest autopsy material is that of Poulsen, in Copenhagen, who gives 91,722 sections with 347 findings of gallstones, making 3.7† per cent., but Poulson states that only 9 per cent. of this material showed any symptoms during life.

Three things influence the figures obtained at autopsy. First, the experience, punctiliousness and carefulness of the pathologist; secondly, the age of the patient; and thirdly, the sex. Peters, at Kiel, found that in persons under thirty years of age the percentage of cases of gallstones was 0.62 per cent.; between thirty and forty years, 3.24 per cent.; between forty and fifty years, 4.44 per cent.; between fifty and sixty years, 6.98 per cent.; between sixty and seventy years, 9.53 per cent.; between seventy and eighty years, 13.02 per cent.; and over eighty years, 16.36 per cent. The figures given by Rother of Munich are one to thirty years, 3 per cent.; thirty-one to sixty years, 6.9 per cent.; sixty-one and over, 19.2 per cent. Schroder of Strassburg gives the following figures: Under twenty years of age, 2.4 per cent.; twenty-one to thirty years, 3.2 per cent.; thirty-one to forty years, 11.5 per cent.; forty-one to fifty years, 11.1 per cent.; fifty-one to sixty years, 9.9 per cent.; sixty and over, 25.2 per cent.

*Etiology.**—A perusal of the American publications evidences a unanimity of opinion that in the United States women are affected between three and four times as often as men, and this proportion between males and females appertains at all ages. The same is true of French and German statistics. Reinelt found in subjects between the ages of fifteen and thirty years gallstones in 1.3 per cent. of the men and 3.8 per cent. of the women. From thirty-one to sixty years the figures were 6.4 per cent. for men and 14 per cent. for women, while for over sixty-one years the figures were 17.9 per cent. for men and 25.4 per cent. for women. For the years from 1901 to 1906, 386 operations were performed for gallstones at the Heidelberg clinic; of these, 46 were men and 340 were women; in other words, there were seven times more women than men. This difference is attributed to the sedentary habits of women, influence of tight lacing, repeated pregnancies, and puerperal infection. These etiological factors must have consideration in the treatment.

In speaking of the direct etiology we must consider everything which could produce stagnation of the bile flow. Among these we must consider compressing clothing, insufficient bodily exercise, dislocation or compression of the bile ducts by tumors or cicatrices. Among the causes which are little recognized I wish to call attention to one of which I have convinced myself repeatedly at autopsies; that is, enteroptosis, and gastroptosis especially. The displacement of the stomach may cause traction upon the hepatoduodenal ligament. This I have frequently seen at abdominal sections undertaken for gallstone.

*Paper read by title at the annual meeting of the American Therapeutic Society in Richmond, Va., June 7 and 8, 1918.

†In the above statistics by Poulson an arithmetical error must have sneaked in, for 347 does not constitute 3.7 per cent. of 91,722. I calculate that to obtain this per cent. he must have had 3,393 cases of gallstones at autopsy.

*For the History of the Clinical Recognition of Cholelithiasis, see J. C. Hemmeter in Sajous' Analytic Cyclopedia of Practical Medicine, Seventh Edition, Vol. III, p. 275-276. Also Die Krankheiten der Leber, by Quincke and G. Hoppe-Seyler, in Nothnagel's Specielle Pathologie und Therapie, Band 18, p. 180-188.

Another cause is dislocated or floating kidney. Then there seems to me to be a form of atony of the musculature of the gall bladder, which in some way is produced by the traction caused by dislocated abdominal viscera in enteroptosis. The tugging upon the splanchnic and abdominal branches of the vagus interferes with the reciprocal innervation that exists between the sphincter at the papilla of Vater and the musculature of the gall-bladder. A close relationship seems also to exist between gallstone disease and pancreatitis.

As the successful treatment must be based on a knowledge of etiology, we must repeat the statement of Naunyn that two conditions are necessary for the formation of gallstones: First, stagnation of the bile flow; and secondly, bacterial infection. Up to the present time this is still acknowledged to be a clinical axiom, and was first pointed out by Naunyn in 1892 in the "Klinik der Cholelithiasis," a brilliant classic on this subject. Throughout the many volumes of *Mitteilungen aus den Grenzgebieten der Medizin und Chirurgie* this eminent clinical philosopher has given us the benefit of his broad experience and conservative critical judgment. According to him, the modern era of cholelithiasis begins in 1892. The significant progress of surgical technique in this period is especially noticeable in the American literature on the subject, and this is so great, and comes from so many able operators and surgical writers in the United States, that I deem it inexpedient to cite their experiences in an article that is to be limited to the purely medical treatment of this condition. But I cannot pass over stating one impression that I gain from American surgical literature, namely, that the so-called early operations have in general been given up, and that the special field for the surgeon is the chronically recurring cholelithiasis. Especial indications for operation are: First, the infectious cholecystitis; and secondly, chronic obstructions of the biliary ducts.

In my articles already quoted I have dwelt on the chemistry of cholelithiasis. The stones consist of cholesterin, calcium, and pigment. The calcium occurs in the form of bulirubin-calcium, calcium carbonate, and calcium phosphate. Bulirubin calcium and the inorganic calcium salts are insoluble in the bile, but as normal bile never contains so much cholesterin that it could not dissolve still larger amounts it is probable that cholesterin stones can be dissolved to a considerable extent in human bile. Cholesterin is kept in solution by the bile salts and the precipitation of cholesterin from bile may be produced by withdrawal of these salts.

A remarkable difference of opinion exists between clinicians and physiologists concerning the derivation of cholesterin. Naunyn is of the opinion that the mucosa of the gall-bladder furnishes the cholesterin as well as the calcium of the gallstones, and thereby furnishes an explanation of the local origin of the gallstones in the gall-bladder. Physiologists, however, know that cholesterin is not formed by the gall-bladder or the liver, but is very widely distributed throughout the body, and that it is only eliminated by the liver cells from the blood, which collects it from the various tissues of the body. Cholesterin is a constant constituent of the blood. That it is an excretion is illustrated by the fact that it is eliminated in the feces, but the contrary view has been suggested, also, namely, that the cholesterin is in part reabsorbed and used again in the formation of new tissues. It is insoluble in water and dilute saline liquids. In the bile it is held in solution by salts of the bile acids. I wish to add in explanation of Naunyn's view that the cholesterin is formed by the mucosa of the gall-bladder, that this has reference only to the inflamed gall-bladder. It is, therefore, a pathological production of cholesterin that he has reference to.

Numerous other American as well as foreign authors have investigated the production of gallstones by the intermediation of bacteria. Most of them show conclusively that the presence of bacteria increases and accelerates the precipitation of cholesterin. Heyrovesky and Exner succeeded in producing a decomposition of the bile salts by the addition of the typhoid bacillus and the colon bacillus. By this the cholesterin was also precipitated, because it is held in solution by the bile salts. Kramer succeeded in producing precipitation of cholesterin by inoculating animals with the typhoid and the colon bacillus, contained in tubes of bile bouillon cultures. Heyrovesky had arranged a scale of bacteria, graded according to the intensity and quickness of their effects. The organism which acts most promptly and most intensely, according to this investigator, is the typhoid bacillus. The next in order is the colon bacillus, and the weakest in their effects are the pyogenic cocci, streptococci and staphylococci. His conclusion that the latter cocci could not be the primary and immediate infective agents in the formation of gallstones, but are by him supposed to be causative of the secondary or hematogenous infection of the gall-bladder, is not confirmed by American investigation, particularly by those of Rosenow.

About one-fourth to one-third of the total dry mass of the feces consists of bacteria. That amounts to 4.5 to 5.3 grams in twenty-four hours. The character of food, though it may influence the variety of bacteria, has no influence on the quantity. According to Weinert, sour milk is capable of reducing the amount of the bacteria to about one-half that above quoted.

Meconium of new-born infants is sterile. After the first breast milk is swallowed we find *Bacillus bifidus* of Tissier and *B. acidophilus*. A diet of cow's milk gives rise to *B. coli communis* and *B. lactoaerogenes* (a few streptococci); on a meat diet there are *B. coli gracilis*, *B. lacto communis*, yeast, *Sarcinæ*, and *B. acidi butyric*, *B. subtilis*. According to Metchnikoff, the principal putrefactive bacteria are *B. putrefaciens sporogenes*, *B. welchii*, Oppler-Boas bacilli, and the bacillus of Hauser-Bienstock.

In considering the relative importance of the factors of stagnation and bacterial infection in the pathogenesis of gallstones, two perspectives must be held in mind: First, the factor productive of the precipitation either of cholesterin or of bilirubin calcium; secondly, the particular species of microorganism and its derivation. Among the normal bacterial inhabitants of the intestines above mentioned only the streptococci, *B. coli*, and the *B. welchii* come into consideration. Among the abnormal microbic invaders of the digestive canal we must consider the typhoid bacillus, staphylococci, pneumococci, and the tubercle bacillus. Mieczkowski found in

twenty-three cases of cholelithiasis *B. coli* eighteen times, either in pure culture or mixed with staphylococci and streptococci. Chiari, in twenty-two cases of typhoid fever, found the typhoid bacillus in the gall-bladder nineteen times. The injection of a culture of typhoid bacilli without ligating the common gall duct, produced no infection. These experiments therefore demonstrate the necessary cooperation of the stagnation of the bile. In thirty-two cases of cholelithiasis, Létienne found the following bacterial infections: *B. coli communis* eleven times, staphylococci seventeen times, streptococci twice, pneumococci once, tubercle bacillus once.

That a progressive, infectious inflammation of the wall of the gall-bladder and of the bile ducts is necessary for the development of stones has been demonstrated by the experiments of Mignot ("L'Origine Microbienne Des Calculs Biliare," *Archives Générales de Médecine*, Aôut, 1898). The same experiments emphasize the factor of stagnation. Mignot filled the gall-bladder of rabbits and guinea pigs with sterilized cotton or gauze into which he brought a drop of attenuated culture of a virulent colon bacillus or staphylococcus. He then sewed the bladders shut with catgut. Three weeks later the bladders were again opened. They had now become thick-walled and rigid. A thread 2 centimeters long was passed through the wall of the larger end of the gall-bladder so that it remained freely suspended in the lumen. The wound was sewed up a second time. Six months later hard stratified stones, consisting exclusively of cholesterin, were found in more than one-third of the cases in the biliary passages of these animals.

If these special bacteria were introduced simply on silk threads or sand grains, and thereby a more or less intense cholecystitis was created, a precipitation of the bile was produced, but the process did not lead to stone formation.

Next to bacterial infection, therefore, the most essential causative agent is a paresis of the musculature of the gall-bladder and bile passages, or some form of obstruction.

In the various surgical procedures that have been employed for the cure of this disease surgeons have had in view almost exclusively the question of infection and the bacterial causes. When a cholecystectomy is performed this is the exclusive view that the operator has in mind, but another and equally important element demands consideration, if the views of Naunyn and Frerichs are correct. The former held that the cholesterin was derived from the epithelial cells of the gall-bladder and Frerichs assumed that the calcium to which the bilirubin and the fatty acids are generally bound is not derived originally from the bile but is a product of the mucosa of the bladder. If these statements were correct, the removal of the gall-bladder would not only be urgently necessary to remove the bacterial etiology and prevent the source of infection but at the same time to obviate the recurrence of deposition of calcium salts and cholesterin.

The percentage contents of human bile in calcium phosphate is 1.7 (Jacobsen) and in fresh dog bile Hoppe found 0.04 per cent. of phosphate of calcium and 0.03 per cent. of carbonate of calcium. Therefore, the percentage contents in calcium salts found in normal bile would be sufficient for the formation of stones without drawing in a hypothetical calcium and gall-stone secretion by the gall-bladder. Cholesterin and bilirubin calcium are both soluble in sodium glycocholate and also in alkaline liquids. Whenever the bile becomes acid in consequence of long stagnation, or abnormal secretion of gall-bladder mucous, then the sodium glycocholate is split up into its constituents, namely, glycocol, cholalic acid, water and a sodium salt. The consequence is that bilirubin is precipitated as a calcium salt and then cholesterin, and eventually also sodium taurocholate. These processes can occur under the abnormal condition of stagnation.

A. Dochmann (Theorie der Gallenstein Bildung, 1889, *Vratch*, No. 3. Abstracted from Maly, Jahresbericht, Band 20, p. 271) analyzed the liver bile and the gall-bladder bile separately. The bile in the bladder was drawn after ligation of the cystic duct. In these separate analytic determinations he found considerable difference between the two samples. In the bladder bile, the sodium was reduced and the potassium increased, as compared to the bile drawn from the hepatic bile duct. Now, the increased content of calcium reduces the solubility of the bilirubin and thereby leads to the precipitation of bilirubin calcium and of cholesterin.

In this controversy between those who hold that precipitation of bilirubin calcium and cholesterin from the bile as it comes from the hepatic duct is possible and those that hold that the epithelium of the gall-bladder secretes these substances, a more recent pathological and chemical study is of interest. I refer to the work of Achoff and Bacmeister (Die Cholelithiasis, Jena, 1909). These investigators believe that in most cases of inflammatory cholelithiasis there has been a non-inflammatory stage which preceded. They also set up the principle of different chemical origin of the different varieties of gallstones. They claim that the radiated cholesterin stone is formed singly and exclusively as a consequence of bile stagnation and without the cooperation of bacteria, but the cholesterin-pigment-calcium stone and the stratified cholesterin-calcium stone, as well as the pigment-calcium stone, are of inflammatory origin. These conclusions are based upon the following consideration:

The structure of the radiated stone is purely crystalline. From a center of crystallization rods of unequal length radiate in all directions toward the periphery. These cause the uneven surface of the stone, which is very porous, contains an albuminous skeleton structure and very little calcium. This stone is found only in gall-bladders that are not inflamed, simply in a state of stagnation. The morphology of this stone is indicative of a very slow process of deposition of its contents by crystallization from the bile. Its chemical composition corresponds to the composition of the normal bile, not of the bile changed by inflammatory processes. It is this type of gallstone that can be produced from the normal bile without infection by simple chemical decomposition. The radiated cholesterin stone occurs almost exclusively as a solitary stone.

Bacmeister experimentally proved that precipitation of crystalline cholesterin from stagnated bile could take place in the entire absence of bacteria or albumin. It is true this precipitation could be aug-

mented by the addition of sterile epithelial cells. In these observations he found the proof that the cholesterin does precipitate from simply stagnated bile, not by infection but by sterile autochthonous decomposition of the bile itself, in which, of course, the protoplasmic elements participate.

The material for the formation of the solitary cholesterin stone crystallizes out of the sterile bile. The process is augmented by the scaling off of the epithelial cells of the gall-bladder. By accurate investigations of gall-bladders extirpated by operations or found at autopsy, they came to the same conclusion, namely, that when a single cholesterin stone was present, every sign of inflammation of the gall-bladder was missing and only the evidence of gall-bladder stagnation was found. In order to arrive at this conclusion, it was necessary to study minutely the anatomy and histology of the gall-bladder, of which they give an admirable description. The distribution of the blood and lymph capillaries in the gall-bladder and bile-ducts is minutely described. They assign to the epithelium of the gall-bladder a two-fold function: First, secretion of a pseudo-mucous substance (nucleo-albumin (?). The beaker cells secrete pure mucin. Secondly, the absorption of fat and pigment.

Naunyn and Fink had claimed that gallstones could be formed from myelin, secreted by the epithelium of the gall-bladder. This Achoff and Bacmeister deny.

In connection with the possibility of the recurrence of gallstones, after so-called cures, Aschoff and Bacmeister call attention to the fact that the mucous glands, while they occur normally only in the neck of the gall-bladder and in the cystic duct, proliferate and extend throughout the entire gall-bladder and into the walls of Luschka's duct after inflammatory irritation. These ducts of Luschka extend into the musculature and fibrous tunic. The normal structure of the gall-bladder undergoes certain changes in chronic cases of bile-stagnation. The normal folds are effaced. The muscularis is hypertrophied. A diffuse small-celled infiltration takes place, as a consequence of the increased resorptive processes. Especially the fat absorption is increased in a stagnated gall-bladder. This leads to a dilatation of the subepithelial lymph capillaries. In consequence of this stagnation and the increased internal pressure Luschka's ducts are dilated and often filled with a detritus of a bile-stained mass. On the base of this altered and stagnating gall-bladder the solitary radiated cholesterin stone is formed.

The formation of inflammatory gallstones is entirely different from this. The gallstones which are due to inflammatory conditions of the gall-bladder are the following: (1) Combination stones, showing interiorly the primary radiation of the cholesterin stone and exteriorly a stratified mantle rich in calcium. (2) The stratified cholesterin-calcium stones. (3) The cholesterin-pigment-calcium stones. (4) The largeer oval barrel, or cylinder-shaped stones. (5) The common multiple facetted or mulberry-shaped stone. (6) The bilirubin-calcium stones.

Sometimes one can distinguish several cholelithic generations. It is sometimes also possible to trace different clinical pictures in the precedent history of gallstone disease in connection with these differently shaped stones. The markedly crystalline and relatively calcium-poor stones grow slowly and occur as solitary stones. Those stones that are rich in calcium grow rapidly and are generally found in larger numbers. Aschoff and Bacmeister assert that in the majority of all cases of cholelithiasis a non-inflammatory process precedes, and that definite relations exist between the different stone formations and the various diseased conditions of the gall-bladder.

As long ago as April, 1895, when I gave a demonstration of the first method for duodenal intubation practicable upon the human subject (Johns Hopkins Hospital Bulletin, April, 1895), I expressed the hope that the method might be available for the diagnosis of gallstones from the chemical and physical conditions found in the duodenal contents. (See also Hemmeter, Diseases of the Intestines, Vol. I, pp. 263-272; also Versuche uber Intubation des Duodenums, *Archiv für Verdauungs-Krankheiten*, Band 2, S. 98, 1896, and Band 17, S. 136, 1911.)

This was long before any one else had ever conceived of the possibility of duodenal intubation.

When one considers, however, the widely different chemical composition of these various gallstones and the different clinical history of each as above alluded to, one must be at once impressed with the difficulty of this kind of clinical research. If we are to determine from the bile aspirated from the duodenum not only whether there are gallstones present, but their kind and the condition of the biliary apparatus, we should have reason to expect a different composition of the bile for each chemical type of gallstone. If in one case the stone is built up from the cholesterin of the bile, and in another case from the calcium, and in a third case from the bilirubin and calcium, it must be evident that we can expect no uniform and constant change in the bile that flows out into the duodenum under these conditions. This conclusion has been confirmed by my investigations, for all of my efforts to establish a constant chemical factor in the duodenal contents, and these efforts extend off and on throughout the last twenty years, have led to no definite chemical diagnostic factor discoverable in the bile as aspirated from the duodenum in cholelithiasis.

In an article entitled "Direct Examination of the Duodenal Contents (also Bile) as an Aid in the Diagnosis of Gall-Bladder and Pancreatic Affections" (*Amer. Jour. of the Medical Sciences*, CXLVIII, pp. 490-495, 1914), Einhorn states that the microscopic appearance of the bile is of great diagnostic importance. If it is golden-yellow and clear, it usually indicates a normal gall-bladder. When it is greenish-yellow and turbid, it portends a diseased gall-bladder, which frequently contains gallstones. He states that golden-yellow bile containing mucus is observed in catarrhal jaundice, but he admits that golden-yellow clear bile may occasionally exist, notwithstanding the presence of gallstones, so his first conclusion is vitiated by the latter statement. But I would also add that sometimes greenish-yellow bile which is turbid can be drawn from the duodenum when the gall-bladder is not diseased, because the color may be due to a duodenitis, and occurs also in duodenal ulcer. The remaining conclusions of this article refer to pan-

creatic disease and not to cholelithiasis. In only two instances do I notice a reference to the degree of alkalinity. In Case No. 9, p. 492, the alkalinity is stated as equal to 20, and in Case 16 as equal to 25. I presume this is expressed in terms of the titration method ascertained by 1/10 normal solution of NaOH. Now, the chemical reaction of the duodenal contents, when the hydrochloric acid of the stomach can be excluded, is due more to the alkalinity of the pancreatic juice than to that of the bile. I will later point out that this alkalinity of the duodenal contents is an important factor in the diagnosis, if it can be traced as due to the bile, which, of course, is exceedingly difficult. In the article in the *Archiv. für Verdauungs-Krankheiten*, Band 17, p. 147, I described a case of varying gastric secretion to which I have given the term "heterochylia." This patient had periods during which no gastric juice was secreted, and other periods during which the gastric juice was either normal or excessively acid. When the total acidity of the gastric juice was normal I found that it required 3.5 to 5 c.c. of $\frac{N}{10}$ H_2SO_4 to neutralize 10 c.c. of pancreatic juice. This patient had a small drainage tube inserted in a dilatation of the pancreatic duct after an operation for pancreatic cyst, performed by Dr. L. McLane Tiffany. The case is described fully by Dr. Harry Adler and myself in the MEDICAL RECORD for August 6, 1898. The case is cited here as a rare instance where the human pancreatic juice was studied during life and its alkalinity ascertained; but it was found that the alkalinity varied with the character of the diet. For complete data reference must be had to the original article, and also the articles on duodenal intubation published in the *Archiv. für Verdauungs-Kr.* 1911.

So much must be evident: The alkalinity of the duodenal contents does not inform us concerning the alkalinity of the bile. If Einhorn finds an alkalinity of 25 this may be entirely due to the pancreatic juice. The bile itself, it is true, is alkaline, but only feebly so. Expressed by the above method, the bile that flows from the common bile duct during health has been found by me to be equal to 5; that is, 100 c.c. bile were neutralized completely by 5 c.c. $\frac{N}{10}$ NaOH. This is an average of 12 titrations. Nevertheless, a marked diminution in the alkalinity of the duodenal contents is a significant sign of the presence of disease of the gall-bladder. Should the alkalinity fall below 5 we can assume that both the pancreatic juice and the bile are prevented from entering the duodenum. I have had two cases in which a persistent low alkalinity of this type was followed in from three to six weeks by jaundice.

In estimating the alkalinity of the bile the hydrochloric acid of the gastric juice must as far as possible be excluded and the duodenal juice drawn at a time when the stomach is empty.

The most complete chemical study of the bile—from which most of my figures are obtained, is found in Bottazzi's "Chimica Fisiologica," Vol. II, p. 401, "Il fegato e la bile." The tables Nos. 79 and 80 give the complete results of eight brilliant chemists on their analyses of the mineral contents and the organic contents of the bile.

Liver bile is much less concentrated than gall-bladder bile. Determinations made on gall-bladder fistulæ in man give a total solid residue of about 0.11, but this bile is not normal. The findings are due to the great loss of bile from the body, for normally bile makes an intermediary circulation, being reabsorbed from the intestine and excreted again from the liver. If it is lost through a gall-bladder fistula this must lead to an impoverishment in solid substances. The liver bile contains 3.21 to 4.66 per cent. of solid residue, according to Hammarsten ("Ergebnisse der Physiologie," 4 Jahrg., "Chemie der Galle," p. 4).

The gall-bladder bile contains 15 to 17.03 per cent. of solid substances. There is a reabsorption of salts of the bile which takes place in the gall-bladder and bile duct, and simultaneously with this reabsorption of salts, organic bile constituents are secreted into the gall-bladder. The bile, if drawn at all from the duodenum, must be gall-bladder bile, and, even normally, greatly different in its solid constituents and salts from the liver bile.

The gall-bladder also secretes mucus, which can be precipitated from human bile by alcohol. It seems to be a mixture of nucleo-albumin and mucin. The genuine mucin in human bile is derived from the bile passages, and if there is a marked presence of mucus in the duodenal contents it either speaks for duodenitis or for inflammation of the gall-bladder and bile ducts. A marked diminution in the total solids of the bile, apart from the organic constituents, means that the calcium or the cholesterin or the bilirubin and pigments are being retained for the formation of gallstones. There is a stage of the cholelithogenic process where the stones, after being completely formed, may undergo partial solution, provided the human subject still retains a fairly normal bile secretion. It is known that gallstones formed in man undergo complete dissolution when sewed into the gall bladder of a dog. In this stage the total solids of the duodenal contents may exceed that of normal bile from 3 to 15 per cent. This is the cholelitholytic stage or phase of gallstone disintegration.

There are, therefore, four diagnostic factors to be obtained from the chemical composition of the duodenal contents. (1) Diminution of the alkalinity. (2) Increase of the mucin. (3) Diminution of the total solid residue below the normal. (4) There may be a stage in the litholytic process where the bile as it issues from the common gall duct (*i.e.* in cases where the pericholangitis has not progressed far enough to prevent the issuance of the bile, partly or completely) contains more total solids than normal bile, the excess of solids being then mainly made up of Ca, Cholestrin, Bilirubin, or a mixture of these according to the composition of the calculi. It is conceivable that there are *cholelitholytic* bacteria, *i.e.* microorganisms that disintegrate already existing gallstones.

It has been observed by Naunyn that gallstones which were already partially disintegrated and dissolved when not expelled were reconstructed into new stones by the secretion of the inflamed gall-bladder mucosa, which is rich in calcium and bilirubin.

As regards the color, I should say that normal bile is always yellow, due to urobilin. A green bile is pathological.

If we have in view the factor of infection in a diagnostic study of cholelithiasis, the bacteriology of the contents of the duodenum can afford us very little aid, for even if the bile is excreted into the duodenum the bacterial flora which we succeed in obtaining (if we obtain any) will be that of the contents of the gall-bladder and not of the gall-bladder tissues. E. C. Rosenow has perfected newer methods for the study of the bacteriology of various infections (*Jour. A. M. A.*, Sept. 12, 1914, p. 903), and in the article, which I shall quote more fully, he pointed out that streptococci of a certain grade of virulence and from different sources are capable of producing cholecystitis and gallstones after intravenous injection, and that large numbers of the cholecystitis-producing organisms constitute the nuclei of the stones.

Rosenow describes an interesting case in which cholecystitis developed in the sequence of an acute tonsilitis. The symptoms began ten days after the tonsilitis, and continued three weeks without jaundice. Then the pain shifted, and jaundice began, which deepened for a week. Five weeks after the beginning of the attack Dr. A. D. Bevan performed an operation. There was found a healing area of necrosis at the fundus of the gall-bladder, which was moderately distended with bile containing mucus, and three mulberry cholesterin stones. Cultures made from the bile were sterile, but cultures made from the center of the stones developed streptococci, colon bacilli, and the gas bacillus. An emulsion of the excised piece of tissue of the gall-bladder developed only streptococci. The culture and tinctorial properties of those special streptococci are described by Rosenow.

A dog was injected on January 22, 1914, with the growth of streptococcus from the wall of the gall-bladder, in 90 c.c. of ascites-dextrose broth, suspended in 7 c.c. of sodium chloride solution. On January 24 the dog was lame in the left hind leg, fluid from knee joint was turbid. Cultures were made. January 26, cultures from knee joints showed four green-producing but no hemolyzing streptococci. January 30 the animal was found dead. Examination showed acute cholecystitis, enteritis, pancreatitis, nephritis. The wall of the gall-bladder was edematous 3 to 6 mm. thick, the cavity distended with brownish fluid. A plug of muco-pus closed the diverticulum of Vater. Pressure on the gall-bladder failed to discharge bile until this plug was removed by passing a probe and making firm pressure. A number of dark concretions of the consistency of putty were found in the muco-pus of the gall-bladder and in the plug. The liver was normal. The kidney showed nephritis. The lower end of the small intestine was hyperemic and covered with an exudate containing many streptococci. The stomach, large intestine, adrenals, heart, and thyroid were normal. The bile, the plug of mucus, and the walls of the gall-bladder yielded large numbers of streptococci. The blood remained sterile. Sections of the wall of the gall-bladder showed marked thickening and degeneration.

This extremely thoroughly worked out case demonstrates, first, that a streptococcus tonsilitis may induce a cholecystitis and gallstones in the same patient within three weeks; second, that a culture of streptococci gained from this patient and injected into a dog may produce acute cholecystitis, puttylike masses in the gall-bladder, a plug in the diverticulum of Vater causing complete obstruction, and the death of the animal after eight days.

This contribution of Rosenow's is of such importance that I venture to abstract it in the following:

In five cases, the cultures from the wall were negative and in these the microscopic evidence of any changes was slight. In the remaining twenty-four cases, in all of which increase of thickness and other changes were more marked, streptococci were isolated in all but three and in pure culture in ten. In sixteen cases streptococci were found in the wall when the contents were sterile or contained only colon bacilli. The colon bacillus was found with the streptococcus in only ten cases, once in pure form, once in association with the *Bacillus welchii*, and once with staphylococcus. *Bacillus mucosus* was found in two cases of very acute cholecystitis. In two, diphtheroid bacilli were found and in one the fusiform bacillus was found. The fluid contents, usually bile, were examined in twenty-six cases: In twelve it was sterile; streptococci were found six times, colon bacilli nine times; staphylococcus three times; the *B. mucosus* twice, and the fusiform bacillus once. The center of gallstones were examined in thirty cases. Only two proved sterile; from the rest streptococci were isolated in all but three, fourteen times in pure form and five times in association with the colon bacillus; the center of the stone, in one case, showed the typhoid bacillus in pure form while the center of two stones and the wall of the gall-bladder in a case with a clinical diagnosis of typhoid cholecystitis showed streptococcus in pure culture; in two cases the center of stones contained colon bacillus and the *B. welchii*, and one of the latter organism only; in some instances, streptococci were demonstrable in smear preparations from the center. Cultures from other portions of stones were usually sterile. The adjacent lymph-glands were examined in five cases. Streptococci were found in four, pure in three cases and in association with *B. welchii* in one case. In the cases in which a pure culture of the streptococcus was obtained from the tissue of the gall-bladder there seemed to be a definite relation between the number of colonies which developed and the degree of change, especially if relatively recent inflammation was present.

A comparison of the results obtained from the bile, the stones, and the wall of the bladder, in the individual cases, shows that a bacteriological examination of the fluid contents gives trustworthy results only in the acute stage of the disease; during convalescence and in chronic cholecystitis the results are of little value and may be misleading. In chronic cholecystitis the bacteriology of the center of the stones is similar to that of the wall of the bladder.

The effect of the various organisms on intravenous injection has been tested in dogs and rabbits. All of the five strains of streptococci isolated from the wall of the bladder, one strain from an adjacent lymph-gland, and two out of five strains from the center of stones exhibited marked affinity for the gall-bladder soon after isolation, and frequently produced no lesion elsewhere. Varying doses produced cholecystitis in nearly every animal injected. The severity of the lesions in the animals often corresponds to that found in the cases from which the strains are isolated. This affinity is soon lost, however, on cultivation as well as on animal passage. Five strains of colon bacilli, the one strain of typhoid bacillus, and one strain of the bacillus mucosus in no instance showed any tendency to localize in the gall-bladder. It was not possible to produce cholecystitis with the streptococci by injecting them into the portal system, even with strains which produced cholecystitis practically every time when injected into the vein of the leg, and only localized cholecystitis developed at the point of puncture when the injection was made directly into the gall-bladder. In the animals which lived for a time, there was not infrequently observed the beginning formation of gallstones containing numerous streptococci similar to the conditions found in several of the patients.

The strains of streptococci from the different cases show a striking similarity and resemble closely those from ulcers of the stomach. They produce either small,

moist, grayish-brown or grayish-green, non-adherent, non-hemolyzing colonies on blood agar; they ferment mannite, lactose and salicin; they produce short chains in liquid mediums with clumps of cocci somewhat resembling staphylococci; they are of a rather low virulence, yet somewhat more virulent than strains from gastric ulcers, as manifested by their resistance to phagocytosis, by the smaller dose necessary to kill, and by the fact that, when cultivated for a time, they acquire affinity for the stomach and duodenum while the strains from ulcers, when passed through one or two animals, acquire affinity for the gall-bladder at the same time as they lose affinity for the stomach.

On animal passage, two of the strains produced both cholecystitis and pancreatitis, the lesions in the latter being most marked in the head of the pancreas.

The lesions most commonly observed other than cholecystitis, when these strains are injected especially in rabbits, are: ulcer of the stomach, hepatitis about the gall-bladder, myositis and myocarditis, arthritis, appendicitis and colitis. The common presence of streptococci in the wall of the infected gall-bladder and in the center of gall-stones, often in pure culture, while absent from the bile and their affinity for the gall-bladder in animals are strong evidence that streptococci are the cause of cholecystitis in man far more frequently than believed and serves to explain the good results reported by some as following cholecystectomy in cases of myocarditis, arthritis and other conditions.

So far as the diagnosis of the bacterial cause of cholecystitis from the contents of the duodenum is concerned, these studies of Rosenow are discouraging for the efficacy of duodenal intubation in this direction, inasmuch as the bacteria which have caused the cholecystitis are not present in the bile as issuing from the common gall duct. They cannot even be detected in the blood, but were found only in the wall of the gall-bladder itself. The problem is more promising of solution when we are dealing with the Eberth bacillus of enteric fever. If this is the cause of the cholecystitis, it is as a rule present in the bile coming from the common gall duct, and it is this class of patient that constitute the so-called typhoid fever carriers.

The bacterium which is the cause of the gall-bladder infection cannot always be isolated from the liquid contents (the bile), although it may be from the wall of the bladder and the center of the stone.

It is not necessary to undertake puncture of the gall-bladder through the intact abdominal wall, as Levy and Naunyn have done, in order to endeavor to ascertain the specific mecroorganism. This can be obtained by duodenal intubation, often gentle massage of the gall-bladder through the abdominal walls, by setting up of the bile evacuating mechanism by injecting HCl and albumoses into the duodenum.

In case there is an obstruction of the cystic or of the common gall duct, this procedure cannot prove successful. It is therefore necessary first to find out whether these ducts are permeable. The most practical method to ascertain this is the examination of the stools. If there is fecal acholia, then duodenal intubation can bring no bile. I must add, however, that there have been two cases in my experience where I obtained bile in quantities of one-half to one and one-half c.c. even when the chemic test and appearance of the stool gave no evidence of it. It is possible that the small amount of bile that reached the duodenum was reabsorbed before it reached the colon.

But if any bile reaches the duodenum at all it can be aspirated by the method of duodenal intubation which was first practised by me in 1897, in the University of Maryland Hospital. Physiologically, the sphincter at the papilla of Vater opens only when the gastric chyme spurts into the duodenum; when the stomach is empty there is no evacuation of bile, but I will show later that this sphincter can be made to open by injecting a solution of hydrochloric acid and pepsin into the duodenum. It has been said that hydrochloric acid by itself will effect this, but it is more efficient if pepsin is added. The most efficient substance to effect the relaxation of the sphincter at the common bile duct is a filtrate of human gastric contents obtained from a normal individual.

All of these substances have a certain degree of acidity which has to be ascertained beforehand, to deduct the amount of 1 10 norm. KOH necessary to neutralize their acidity in calculating the alkalinity of the duodenal contents after they are drawn. 1 c.c. of normal gastric filtrate from a human individual may cause the evacuation of between 10 and 12 c.c. of bile. A few drops of the HCl pepsin solution suffice; these can be aspirated and the subsequent bile expulsion used, which is, as a rule, free from the injected HCl.

The hydrochloric acid or the filtrate of human gastric contents thus injected causes the formation of secretin from prosecretin, which in turn evokes the secretion of pancreatic juice, and is supposed also to cause a secretion of bile, though not all investigators are agreed on this latter point. (See Falloise, quoted in Maly's "Jahresberichte der Thier-Chemie," 33, 611, 1904.)

Treatment.—The course to pursue in aiming at a treatment of cholelithiasis that is based upon the cause would be to first ascertain the specific bacterium which is causing the infection, and thereafter to obtain a serum by inoculating animals with this special strain of organisms. In one of my cases of chronic cholecystitis with occasional attacks of high fever that followed three months after a severe streptococcic tonsillitis, anti-streptococcus serum apparently cured the patient, for she has remained without symptoms for two years and two months.

There is a justified doubt in this case, for there are periods of two years quiescence in many gall-stone cases, after which the cholelithiasis may again give rise to symptoms. Moreover, according to Rosenow, only the particular strain of streptococci that had been derived from a case of gallstone disease should be used to produce the serum. It is conceivable that the specific strain of streptococci might be cultivated in these cases from the tonsil.

The difficulty will be to secure the proper strain of bacterium which is doing the mischief, but I believe that with patient research by the method of duodenal intubation, and making use of the neurochemical mechanism which controls the sphincter of the common gall duct, marked advances in the diagnosis and therapy of this condition will be made.

The treatment of cholelithiasis has different aspects in view, and varies according to the diagnosis of the conditions present. It will also vary according to the causes of the conditions.

It is necessary to plan a special treatment for the following four conditions: (1) The gallstone colic

with the acute occlusion of the common gall duct and the recurrent cholelithiasis. (2) Inflammation of the biliary vessel and reservoir system (gall-bladder, cystic duct), the acute cholelithic cholecystitis, with its consequences: (*a*) perforation peritonitis, (*b*) diffuse cholangitis, (*c*) chronic cholecystitis, with empyema and dilatation of the gall-bladder. (3) The invasion of the deeper bile passages by the stones, chronic occlusion of the gall duct. The differential diagnosis and management of the various types of icterus. (4) The consequences and complications of cholelithiasis and malignant neoplasm of the gall-bladder.

The principle of non-surgical treatment of cholelithiasis is to bring about a period of quiescent latency in the disease. Complicated infections, and all factors that tend to stagnation of the bile, may have stirred up a dormant disease. Of course, this can be treated by operative removal of the gall-stones and draining the gall-bladder. From what we have seen in the preceding, however, only 5 per cent. of all gallstone carriers ever have symptoms. This makes it clear that there must be a great majority of the subjects of cholelithiasis who harbor their stones throughout life with a comparative degree of comfort, or are not aware that they have gallstones.

I am not at all opposed to the operative treatment of gallstones. On the contrary, I favor it. (See article on "Cholelithiasis" in the Analytical Cyclopedia of Practical Medicine, Volume 3, page 295.) I also there call attention to the technique and value of duodenal lavage in the treatment of cholelithiasis. But there are plenty of patients who refuse to be operated upon, or who never have a second attack, or who have been operated upon already and in whom the cholelithiasis returned; such cases, in short, that demand nonoperative treatment.

For the present I shall pass over one of the most effective therapeutic methods of the internists, namely, the treatment by hot mineral waters and diet.

I wish to emphasize what I have repeatedly condemned, namely, the employment of so-called cholagogues, especially a number that appear to be proprietary articles. Any agent that causes a hemolysis of red blood cells will increase the flow of bile, and the same effect is produced if a solution of hemoglobin is injected directly into the blood. The bile pigments are excretory products of hemoglobin. Most all so-called cholagogues are hemolytic and also protoplasmic poisons to the hepatic cells.

The use of olive oil, either by mouth or rectum, in large doses, has in my experience not been followed by gratifying results. It has been claimed that concretions can be found in the stools after the oil treatment, and that they are the result of broken down gallstones. I have convinced myself that these concretions are nothing but fat conglomerations, and that the large doses of olive oil, as given by Stewart and Mays, derange the digestion. It would be pardonable if a slight improvement followed the treatment with the substances which I have just mentioned, if we were sure that they did not do harm. Cholelithiasis is such a complicated and variable disease that improvement frequently follows rest in bed, hot Carlsbad or Bedford magnesia water, and hot applications over the liver.

It is entirely irrational to speak of a solution of gallstones by medical means. What the cholagogues are supposed to do is to increase the flow of bile, in order to wash out the biliary passages. If it were really possible to increase the *secretion* of bile it is not at all proved that an *increased* flow of bile through the gall-bladder, common gall duct, and into the duodenum would follow. It is not sufficient to increase the amount of bile secreted. What is needed is an increased flow of bile through the biliary vessels. This is, in the normal individual, prevented by the sphincter of the common gall duct. In 1887 Oddi showed this sphincter anatomically, and he also demonstrated that it is controlled by a group of ganglion cells which regulate the constriction and relaxation of the sphincter. See illustration in Luciani's Physiologia del Uomo, Vol. 2, pages 187 and 188.) The same sphincter was studied by Hendrickson (*Johns Hopkins Hospital Bulletin*, September, 1898.) Oddi found that the force with which the sphincter closes can only be overcome with a column of water of 700 mm.

Freese (*Johns Hopkins Hospital Bulletin*, June, 1905) found the force of the maximal contraction of the muscle of the gall-bladder to be 220 mm. of water; almost the same pressure was found by Haidenhain. This pressure varies according to the animal experimented upon, and Naunyn assumes that the force with which the sphincter of the common gall duct is kept closed is equal to a pressure of 700 mm. of water. This is Oddi's estimation. Such a pressure is far greater than could be overcome by an augmentation of bile secretion, for the secretory pressure of the human bile apparatus doesn't go beyond 250 to 300 mm. of water. Whenever the pressure in the bile ducts exceeds this the hepatic cells no longer secrete into the gall ducts, but any bile that is formed is received into the lymph vessels which surround the hepatic cells, and eventually reaches the thoracic duct.

The reciprocal neuromuscular control between the sphincter of the papilla of Vater and the muscle of the gall-bladder can only be set up normally by the products of gastric digestion, and in such a manner that the sphincter at the orifice of the common gall duct is inhibited when the gall-bladder contracts, and *vice versa*.* To produce an increased flushing of the gall ducts and gall-bladder with bile, the sphincter of the common gall duct must be opened. Physiologically this occurs during gastric digestion and evacuation through the pylorus. Assuming that cholagogues could augment the formation of bile, as yet there is no evidence that they can open the sphincter of the common gall duct, the tonus of which will remain 400 mm. of water pressure higher than the pressure of bile secretion.

*The reciprocal innervation of the gall-bladder and biliary ducts has been studied by Doyon (*Archives de Physiol.*, 1894, p. 19).

Egg Intoxication.—According to Linossier egg intoxication must be distinguished from egg anaphylaxis. The egg may contain a toxalbumin which is destroyed by heat. Poisoning from this source is therefore readily prevented.—*Le Progrès Medical.*

PLEA FOR A MORE SYSTEMATIZED STUDY OF A PATIENT'S LIFE NEEDS.*

THE BREAD LIFE.

By J. STEWART DOUBLEDAY, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, THE NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL

NEUROLOGISTS nowadays are on the lookout for cases of life-maladjustment, and the spirit of the times is socially remedial and constructive. We all endeavor most laudably to view a patient's ills in the light of his personal relation to life in general, and thus to suggest more permanent, because more socially sound, measures for his relief. This I recognize, and it is not with the notion of advancing something really new that I ask your attention to the adjustment problem, but simply because it has repeatedly come home to me that we lack a convenient system for its daily individual solution. Also, by way of preface I wish to remark that in ordinary office cases, one main life tract, that of sex (the love life of Jung) has been explored out of all proportion to the other three, and that therefore its importance (not biologically but psychologically speaking) has been by comparison overestimated.

To begin with then, we must realize that we are now contemplating individual life or conscious continuance, which connotes two essential instincts—the self instinct and the race instinct, which may be further divided: The self instinct into self preservation and self progression; the race instinct into race preservation and race progression. We are viewing primitive essentials only, all else being subsidiary or superstructural. And these four great emotional life tracts, based on the two primordial needs of self and race, compose a satisfactory working map for our profitable review of the basic demands of individual human motives. It is the purpose of this paper to deal with self preservation, which for convenience and strength of concept can be termed the food life, or better perhaps, because of the traditional force of the phrases "making our daily bread," "bread is the staff of life," "bread-winning," etc.,—the Bread Life; for while many other factors enter into the idea of self preservation, the principal and characteristic factor is by all odds that of food.

This "bread life" consists of two factors—food and the fight for it, nutrition and livelihood. The first factor, the need of nutrition, present of course at all ages, becomes progressively very gradually less important as the years go on, as the period of decline approaches and succeeds that of growth and maturity. The food needs of the child are greatest, and so on proportionately down the scale to old age; and this side of the question—the actual food or nutritional necessity, the use of food, being almost wholly biological, we pass on directly to that of food winning, which is, as all know, quite another matter, and one that intensely concerns the daily practice of the neurologist.

Maladjustment from the problem of insufficient livelihood, the worry and fatigue, the increasing strain, the actual illness consequent on or incident to failure to make enough money for self and dependents is so common and so intelligently (even if in the main unsuccessfully) dealt with by most neurologists and many good family physicians, that it would seem superfluous to discuss the subject further, were one not brought daily face to face with the fact that, despite the energy we put to its consideration, we should put more. The army of defeated men and women who are taking nux vomica or thyroid or galvanism for some compensatory symptom (too often their only positive compensation) who would be relieved entirely by a raise in salary or news of an unexpected inheritance is so distressingly large that we should at least be systematically sure we shall not neglect any individual of its forces, who, it must always be remembered, are recruited from the seemingly rich and well-to-do as well as from the poor. Of course where a patient's means are frankly insufficient, even though he is working hard, we cannot always help him very much. Even in such cases, however, if we are dealing with ordinary intelligence, an examination of the livelihood ground will yield some profit if, only at its conclusion, the patient has been made to realize the underlying cause of his seemingly inexplicable insomnia or tremors or feeling as if his head would burst. Sometimes we may be successful in doing more. Last month in the clinic I talked with a man of 40, single, no dependents, who had been earning a bare subsistence in a tailor shop, but this extremely confining mode of livelihood making him nervous and sleepless he gave it up and became a dish carrier or "passer" in a hotel, which, also bringing in but a bare pittance, proved equally unsatisfactory and did not diminish his neurosis. Now this man is no weakling. He is educated, intelligent, even intellectual, and with many indications of character and developed will power. He has a gift of human association, public speaking, gaining the confidence, and, in a certain moral and impractical sense, the leadership of his fellows. He would make an excellent teacher, or secretary perhaps of some large civic or philanthropic concern. At all events he is freshly encouraged by this view of his case, and encouragement based on real understanding is so truly effective a force that very possibly his efforts henceforth, based on a renewed faith in his powers, may lead him to a distinct betterment of his condition. Surely neither bromide nor veronal could have done even this much.

Then the spending side as well as the earning side must come in for scrutiny. To cite an instance: A stock-broker earning probably forty thousand a year came to me suffering from claustrophobia; he could not go in trains, to church or theater without a sort of terror. He suffered agonies on the floor of the Exchange. No treatment availed till it came out that at the time of a seemingly impending business failure, on the Sunday following a night of most unusual mental strain, he was taken dizzy in church and thought he should die, yet hoped he would not, not alone from fear of death, but shame of making a scene—a state probably symbolic and compensatory, I believe, of his business difficulty. And now when business depressions occur he is inclined to this anxiety state. Explanation as to the nature of his disorder and improved condition of business have helped him markedly and equally. We must always remember that men are ashamed of

*Accepted Entrance Paper for the New York Neurological Society, June, 1918.

not making good at a livelihood, and ordinary questioning in that respect is therefore not always enough to elicit the actual circumstances, for just because of the primal intense biological necessity of going forth to get food, the sensitiveness consequent on failure thus to achieve is rooted in what might be termed an insulted instinct, which causes a crippled emotional condition leading to a consciousness of something very like biological inadequacy. It is a truism that an individual prizes far more his inherited than his acquired attributes. Generally speaking, men are far vainer of pure race, good lineage or native abilities than of trained acquirements or hard-won social position. Who would not rather be called a born genius than a man of made aptitudes? And this is well, perhaps, for the conservation of racial excellence, and is not mere vanity at all, but an instinctive pride in what is in the long run worthy, of what lasts beyond the individual life-history, of what is biologically best. Thus with the power of going out into the arena of the world and bringing back the livelihood prize, man hesitates to admit his failure because of the suggested inferiority. Very likely he doesn't know this, but his instinct surely does—and good or bad, moral or unmoral, instinct is master. And if the neurologist is wise he will not induce his patient to make too open a confession. Here, even as in sex matters, the truth-seeker should heed Ibsen's character called the Boyg, who, in blocking Peer Gynt's path up the steep mountain of knowledge, bids that impatient aspirant "Go roundabout." It is wonderful advice, and will certainly hasten one's journey to a troublesome peak. I think it is over the portals of Aberdeen University that the following adage is inscribed—and this I particularly recommend to all who deal in the mysteries of psychological therapy: "He says. What does he say? Let him say."

Well at first he will likely say, "Doctor, I've a pain in the back of my neck that runs down the spine and up into the head and sometimes shoots straight into the heart." It takes a while—two or three visits, perhaps—before he will want to translate this into terms of creditors and notes falling due. But in such a case, if we don't carefully attend, he will brazen out the whole matter, from the biological fear of being thought inferior, and give us the impression that his secondary sex or domestic difficulties (because a man in money trouble always has secondary psychologic upsets) is the main trouble. And then all treatment must go for naught. What to do? Well, the first canon of treatment is accomplished after he in his own way and at his own time has made a clean breast of it. This shows that he has faith in you, in somebody, something. The next and at least equally important indication is to restore his faith in himself, to make clear to him what is probably the truth, that his livelihood difficulty is transitory and circumstantial and has nothing in it of the essential, the biologically feeble. Drive home to him the point that if this actual inferiority existed he would be willing to accept its mandate and not be writhing, sensitive and rebellious. At the same time don't forget his physical ills. That is a great mistake. They are actual, no matter whence they arise. If the Christian Scientists have made us more clearly cognizant of the value of the word Faith, so have all the little body healers, osteopaths, chiropractors, what not, helped us on to a recognition of the necessity of physical touch. All those rubbings, kneadings, strokings, vibratings, have a distinct symbolic value. A sick man comes to be healed, whatever the infirmity, and from time immemorial the warm, friendly, distinctively human touch of him who does the healing has been as a magic wand to release the patient from his ills. When a dog is hurt we say "poor fellow," and pat and stroke him kindly. Don't neglect it with your fellow being, and then the other touch, that of the pocket-book, will come much easier.

Cases of this kind, frankly depending on difficulty in breadwinning, are, as we all know, of daily occurrence in our work. Let us pass on to that more interesting side of the same problem, the instinctive necessity of a fight for livelihood—not the point of the livelihood itself, but the essential fight to obtain it—an angle of the question which it seems to me has been rather neglected.

Man, like all other animals, originally had to battle physically for his food; else he didn't get it. When the flesh on which he and his family had subsisted was gone he girded his loins, took down handy knife or spear and started out on a meat quest. Not much difference here between man and tiger. Both were fierce, both showed their fangs and woe betide what came in their way. We all know what happens to the tiger when we cage him and feed him and liberate him from the magic lure of the mysterious food forest which his forbears have ranged since the first sun warmed their stripes. He shrivels in spirit, grows restless, paces his cage, feels life to be tamely inadequate, rebels at the crowning futility of this civilizing force which would debase him from the glory of a tiger to the purring level of a hearth cat. Now, man is not a tiger, but there is much of the tiger in him, and when we take all the wild beast out of him we miss something in him; also he misses something in himself, though he does not know just what it is. Yes, the open fight and the wily stratagem (which is a part of fight) in the vast, unending conflict of food getting are primal human needs, and no picture has quite such a droll pathos as that of the energetic adventurous man who has too early salted away his flesh pots, and knowing that his nutriment is secure without further effort on his part, dilates to his friends on his wonderful good fortune; yet who, when those friends have departed, yawns away the heavy hours and reads about calories and "How to Prevent Old Age."

I have now in mind one such individual. He is a lanky, big-limbed Westerner of 55, one of the erect, hustling, nimble-witted captain of industry types. He began life as a clerk in a country store at fourteen, and, totally unaided, worked up for himself in real estate till at 48 he owned a juicy slice of the New City of Cleveland, and soon after managed with difficulty to retire from the many sided corporations of which he was an important member. After this, on the further advice of his family physician, he gave up his own most interesting business, in which he had become a millionaire, and proceeded so to arrange his life that it would declare, with no work, maximum dividends of daily happiness. Needless to say, such a stock, being

watered with dilute artificialities instead of enriched with robust necessities, never yields up to expectation. This gentleman is not happy at all; he is, in fact, completely miserable. Golf, billiards, travel, theaters, family and friendly associations, and interest in religion and war-relief work, though he has all of these and employs them assiduously as diversions, avail little, for they do not meet the central need, which is, in his case, the cry for fulfillment of the food-fight instinct, the spark that burns in the bosom of energetic man and tells him to go forth and provide. Unluckily in his case the provision is already secure, and there could be no deeper misfortune.

Well, what does he eventually do that brings him to the neurologist? He makes compensations. Innately realizing that the final giving up of business is the cause of the maladjustment, yet burning to deny it, to excuse it to the world, to himself, and particularly to his family, who are perhaps inclined rather cruelly to see paternal matters in their true light, he believes or strives to believe that he is ill, and has been compelled by illness to this surrender of his normal activities. "You wouldn't have a sick man plug on forever, would you?" "Keep a lame horse in harness till he breaks?" High blood pressure, uric acid diathesis, nephritis with hypertension (resounding titles for the similarly afflicted) headaches that drive him frantic until they have achieved their aim in driving all others frantic, vertigoes, dyspneas, neuralgias, fears of appendicitis—indeed the whole hypochondriac gamut. We see to what absurd yet tragic physical lengths he is driven by the whip of that still vigorous tyrant, his self instinct for fight. This thrilling force, which one time had been used squarely and successfully against the real world enemy, is now absorbed in trivial and self-debasing skirmishes with the grotesque Bolsheviki of his imagination.

What shall we do with such a patient? Games are good, being sham fights, and it is just this fighting element which ensures their popularity and permanence. The drawback is that he has played the greater game and all else stales by comparison. When possible, if you can't get him back into business, give such a man something with a spice of physical danger. He will take gladly to it—high mountain climbing, conquering the noted peaks one by one, beating across famous deserts. Try him with the Amazon and the Andes or tiger-hunting in India. Yacht-racing is fine, riding cross country, an experience in an airplane—briefly, those sports with most hazard and dash. Then interest him in controversies; anything with scrap in it. He is saved if he goes in for practical politics. But enough is said to bring out my point that due regard must be had for the primitive food-fight section of the Self Instinct. I would simply add—and this is a serious objection to the millennium and indeed to all forms of ideal socialism, where the State safeguards the individual at the cost of individual enterprise—that men on salaries who have no definite hope of advancement beyond the salaried stage and thus striking out for themselves, are far more prone to these neuroses than those whose efforts spell adventure. Put an average man in a good safe business situation year in and year out with reasonable compensation, yet with no particular hope of ever being on his own business legs, give him love, home, family, friends and leisure for meditation, give him everything, indeed, traditionally conducing to his content except this one satisfaction of his craving for adventure, hazard, essential food enterprise, and what is the usual outcome? Smouldering discontent and a neurosis. You can't shut out a man from the fresh air of his instincts and expect him to thrive.

In pre-war Germany a considerable part of the population, as compared with other countries, was in a measure taken care of, safeguarded and shepherded by the State, and in pre-war Germany all forms of neurosis were extremely common. Has that circumstance nothing to do with the present war? Was there not previous to the outbreak an overwhelming popular suppression of the enterprise instinct, which must have universally welcomed a world upheaval of release? In such a case, though the movement would be national and racial, the root instinct that started it would be individual. The surmise, though presumptuous, is attractive.

Women, too, have this instinct, though in negative form. They are not quite content to fight for the sake of the fight as men are. They want to help man in his fight, to aid, encourage, abet, and above all to hoard. The man brings back the carcass and the woman salts it away for the winter. He risks his life to obtain strange nuts, and she piles them up in hidden crannies against the dark days. Woman is the saver, the consumer, the straw to the masculine brick without which the family livelihood building would come quickly down. She fights negatively, receptively to his positive and initiative, but hers is just as truly as his an overwhelming primal instinct without which release and function she is quite as miserable and "left out" as he. Picture the multitude of women of means who need just this opportunity and nothing else, who have love and associative ties and leisure for contemplation, yet who, because of a good income, which is and has likely always been perfectly secure, miss inevitably and profoundly that wondrous fulfillment of woman's intended activity in upholding man in his daily labor of supply. We all of us know cases where people have suddenly lost all their worldly possessions. Paterfamilias comes home and announces: "The worst is here. I am bankrupt, ruined. I have lost all. Henceforth, etc." And what does wife do if she is a typical woman? Rear up, rant, scream, speak of spring hats? Nothing of the kind. The scene is stereotyped. Sweet tears, supporting silence, words of comfort, deepest joy and contentment in her heart that she can at last be of real help to him, that henceforth her daily efforts to plan and conserve will count, that she must save and hoard wisely, that she is not longer what such persons dread beyond measure and yet which so many become—a woman who is insignificant. And she is right. Any average woman of a good sort can be a member of committee, head an auxiliary, do semi-public and civic work and the countless general and impersonal duties of modern feminine existence, but only one woman can adequately help one man. The treatment of women who are at odds with life—and these are of vital interest to the neurologist—is, of course, first to find out the cause of the maladjustment. Well, more likely than not

the trouble is right here in the Bread Life Caption —either their daily bread comes too hard or too easily. And each case carries its own interpretations and recommendations for remedy.

My point of view is now made clear, though, of course, only in briefest outline, the subject being of the magnitude of life itself. And if I have drawn attention to the troubles of the rich rather than of the poor, it is perhaps because I believe that in this one respect they are more likely to be therapeutically passed by as a class. And also, for the sake of brevity and integrity to the main presentation of the matter, I have, in speaking of men, intended to signify typically masculine men, and of women, typically feminine women, thus avoiding that most interesting secondary theme, the relation of livelihood to those of the intermediate sexes. But my concluding word is to suggest that in no patient whose condition is not frankly physical should we neglect a just consideration of the possible maladies of that primary and perhaps all too obvious expression of the Self Instinct—the Bread Life.

INTERNAL USE OF RADIUM.*

By D. C. Moriarta, Ph.G., M.D., F.A.C.S.,
Saratoga Springs, N. Y.

It was only after much mental vacillation that I asked for an opportunity to present a paper on the use of radium internally at our meeting to-day. This was so, not because there is any question in my own mind as to the value of radium as a unique therapeutic measure, but because I appreciated that my conclusions are empirical, as they are largely clinical observations. I do not believe that rational deductions for the administration of a therapeutic remedy in pathological conditions of the human can be drawn from experimental studies on normal animals. It is quite impossible to have "a control" in clinical work, and so one is not able to check up one's work in a definite manner; and without biological and physiological data with which to corroborate my deductions they are open to question.

Whether the action of radium, when administered internally, is autolytic, catalytic, or by its electrical force exerted on the individual cell, as believed and taught by Von Noorden, is beyond my determination. But I do know from my laboratory findings that radium promptly and invariably increases the number of red blood cells. From this single finding it is obvious that the remedy is a potent one and must of necessity augment all of nature's processes, no matter how complex they may be; and I might add whether understood or undetermined. It is not difficult to appreciate that, when a lowered vitality is markedly improved or brought to normal in red blood cells, faulty functional conditions will be corrected by nature. Thus the results might be said to be secondary, though they are usually attributed to the direct therapeutic action of radium, and include a general stimulant and tonic action, the increasing or modifying of secretions and excretions, the raising of suboxidization processes, combating toxemias, stimulating universal cell activity, and so on, *ad infinitum*.

In 1915, Dr. Field read a paper before our local medical society on the efficiency of radioactive waters in cases of faulty elimination, in the course of which he stated that the National School of Mines had found that some of the Saratoga mineral waters were radioactive, while others contained radium in solution. This statement interested me particularly, as it possibly explained a point which I had brought to the attention of our medical men in a paper on the Saratoga waters in 1908. At that time I emphasized the thought that the clinical results obtained from the use of our Saratoga mineral waters were greater than we had a right to expect from their published analyses; and I intimated that there might be an element, or combination of elements, which was not accounted for by the chemist in his analysis. I later concluded that this action was due to their radium content, and after some further investigation became convinced of the value of radium and determined to try it out.

I commenced with 15 milligrams of the element in the form of a soluble chloride, 10 milligrams for an emanatorium, and 5 milligrams with which to activate water. I have continued its use regularly in my practice since that time, as opportuniy presented, with many successes and few disappointments.

Every practitioner meets cases of functional disturbance incident to overwork and nerve strain, associated with the all too common dissipation and gormandizing; in fact such patients have usually abused nature in every conceivable way. These are the cases so classically described by Bishop, and which, as he has pointed out, are prone to and usually do end later in some form of myocardial, cardiovascular, or cardiovascular-renal degeneration. This type of patient is very common in our work during the season.

For years I have been treating such cases after a formulated regime, drawn from the suggestions of Bishop in his few-protein diet, of Kellogg in his vegetable protein diet, and my own personal experience. This regime comprehends the regulation of the diet, the habits, exercise, periods of rest, and the external and internal use of the Saratoga mineral waters.

When treating my first cases with radium, I decided to omit all other measures, and endeavor to determine whether radium possessed the merits so lavishly attributed to it. I took the cases one after another as they came along. The following points were determined in each instance, when they first came to me and at weekly intervals during the period of treatment: (1) blood pressure, (2) blood count, (3) urine: (A) quantity, (B) specific gravity, (C) casts, (D) kidney efficiency (as determined by phenol sulphonephthalein test).

My method of administration and dosage were essentially the same in all cases; clinical conditions did not govern dosage. Each case was treated daily for a period of six weeks; in the emanatorium for two hours, where there were 270 Maché units of radium emanation to a liter of air, with varying quantities of activated water internally, usually a half liter which contained 113,000 Maché units to the liter, and some of the cases had also intra-

*Read at a meeting of the American Radium Society, Chicago, June 10, 1918.

venous injections of radium salts. Three of the cases developed a marked reaction from the treatment (without intravenous injections) which was manifested by increased pulse rate, temperature, nausea and vomiting, and great prostration, lasting in each case about 48 hours. On resuming the treatment, a second reaction occurred in two of them. I finally succeeded in establishing a tolerance for radium in these cases by commencing with a very small dose and gradually increasing it. The number of cases observed were 19, of which there were: 2 gout, 2 arthritis deformans, 3 diabetes, 2 intermittent claudication, 11 cardiovascular-renal disease. The two cases of gout were old ones and had experienced many previous attacks. Both were enthusiastic over the remedy, stating that the attacks were of shorter duration and less painful.

The cases of *arthritis deformans* were decidedly improved, particularly as to the relief of pain, the diminished swelling in the joints, and the increased action. In one of these cases I was too anxious, and used 40 micrograms intravenously, in addition to the usual procedure. The patient became very ill and in a few hours practically collapsed; blood pressure dropped from 230 to 110 mm.Hg. We gave her stimulants and pituitary extract, and after 24 hours she was all right, except for malaise.

The cases of *diabetes* were negative, except for lowered blood pressure and an increased red blood count.

The cases of *intermittent claudication* were relieved, that is, the attacks of pain subsided and remained quiescent for about eight weeks.

The eleven cases of *cardiovascular-renal degeneration* were all rather advanced; yet notwithstanding this fact, they all took on a feeling of well-being and comfort, and the dyspnea, blood pressure and kidney elimination were unquestionably modified. Though the number of cases treated was only 19, yet the following facts stand out so constantly that I accept them: (1) general feeling of well-being and betterment, (2) diminished blood pressure, (3) increased kidney efficiency, (4) decided increase in number of red blood cells, varying from 150,000 to 1,500,000.

The prognosis naturally depends upon how far the pathological process has developed. However, given two cases which are identical in all particulars, if they receive exactly the same treatment, except that one is given radium internally and the other is not, there will be, in my judgment, a very large percentage of betterment in favor of the case which has the radium. How could it be otherwise, with the increased red blood cells with which nature may do her work? Just as a pneumonic may be carried through a crisis, with a large number of cells out of commission, by the use of oxygen which stimulates the remaining cells to increased activity, so radium stimulates and gives fighting material where there is cell life; of course, where the cells are destroyed as in anterior poliomyelitis, there is no remedy.

Duration of treatment. This must be prolonged, as radium is largely indicated in chronic morbid conditions, in which the balance is not only difficult to establish, but in which it is also easily upset.

In conclusion, I would not be understood as thinking, for a single moment, that radium could in any measure replace other drugs, which have a specific and immediate action in controlling conditions in which decompensation is present; neither does it take the place of other measures which are prophylactic or corrective in chronic conditions, particularly myocardial, cardiovascular, and cardiovascular-renal degenerations. Nor does it replace the achievements of Bishop in his few-protein diet, nor of Kellogg with his vegetable protein diet and hydrotherapy, nor of Guelpha and his new fasting treatment of chronic disease (this was presented to the British Medical Association in July, 1910); all of these relieve faulty elimination and correct perverted metabolism, intestinal stasis, fermentation, putrefaction, and constipation, with their resulting toxemias.

It is not contended that radium per se is a specific in any disease. But I do know that it has a specific action, in promptly and efficiently increasing the red blood cells; and it does not detract from the methods of the men quoted to say, that while their measures afford remarkable results they do not materially increase Nature's resources, in so far as red blood cells are concerned. So I feel justified in positively urging the use of radium internally, in conjunction with those or other procedures, as I have been doing for the past two years, with results the same as in my first nineteen cases.

Radium is certainly a valuable adjunct to the carrying forward of Nature's beneficent processes.

OVERFLOWING TEARS (EPIPHORA) AND ITS MANAGEMENT.

By J. A. KEARNEY, M.D.

NEW YORK.

PROFESSOR OF OPHTHALMOLOGY, NEW YORK POLYCLINIC MEDICAL SCHOOL AND HOSPITAL.

THE successful remedial management of this most distressing symptom, overflowing tears (epiphora), depends upon a careful study to determine the cause and when found attacking the same by appropriate measures. Diseases of the lacrymal system make up 3½ per cent. of the writer's clinical opthalmological practice. Diseases of the lacrymal gland produce an excess of tears, but these affections are very rare and are usually of metastatic origin traceable to gonorrhea, influenza, the exanthemata, mumps, diphtheria, and typhoid fever.

Epiphora is a usual symptom in irritations and inflammations of the cornea and conjunctiva. Occasionally it is the result of errors of refraction, extrinsic muscle imbalance, some nervous diseases, neurasthenia, and tabes dorsalis notably, and it may be an early sign of exophthalmic goiter.

The lacrymal drainage apparatus, consisting of the lacrymal puncta, lacrymal canaliculi, lacrymal sacs, and nasal ducts, is found to be faulty in by far the great majority of patients who present themselves for the relief of the overflow of tears and it is essential that the exact portion of this channel that is affected be determined, as the treatment that is to be applied largely depends upon this knowledge.

An occlusion or stenosis of the punctum is determined by dilating it with a canaliculus probe

sufficiently to admit the tip of a lacrymal syringe and then passing a solution of boric acid and menthol into the opening. If the solution finds its way into the nasal chamber the obstruction is at the punctum. If the solution returns, then the stenosis is beyond the punctum. In this event the canaliculus probe is passed in the canaliculus until its tip touches the bony wall, it is then withdrawn and the solution instilled once more in the opening at the punctum; should the solution now reach the nasal chamber the stenosis is in the canaliculus; if, however, the solution returns or passes around the upper canaliculus and out its punctum, the stricture is in the lacrymal sac or nasal duct.

When the punctum is found to be occluded by mucus or other foreign material this may be wiped out by absorbent cotton and the drainage channel subsequently flushed. One such cleansing is usually sufficient.

If as the result of blepharitis marginalis or chronic catarrhal conjunctivitis the punctum is closed, treatment must be directed to the correction of these diseases. In misplaced puncta due to ectropion, entropion, or senile lack of tone of the lower lid the stated operations are done to correct these conditions.

Patients who have a stenosis of the punctum or canaliculus not attended by inflammation will not as a rule present themselves for gradual dilatation with probes as frequently as is necessary on account of the discomfort and pain attending this treatment, and even among the most faithful in this respect the stenosis returns in most instances after the discharge of a case that is deemed sufficiently dilated. At the present time it is advised that the canaliculus be slit in every case of stenosis of the punctum and canaliculus that is definitely made out, and a permanently good result may be reasonably assured every such case.

The canaliculus is slit by first dilating it with a canaliculus probe that is passed as far as the bony wall and then withdrawn; now the tip of a Weber's knife is entered at the punctum with the cutting edge inclined slightly toward the globe and the instrument is passed in the dilated canaliculus until its tip reaches the bone, the handle is then elevated. The incision thus made is kept open by dropping liquid petrolatum at frequent intervals in the conjunctival cul-de-sac. If the sides of the incision become adherent a probe is passed between them to keep them apart.

When the constriction is made out to be in the lacrymal sac or nasal duct the canaliculus is first slit and a rapid dilator (Ziegler's) is passed through the drainage channel into the inferior meatus of the nose. The passage of the rapid dilator is sufficient to keep the channel patulous in 25 per cent. of these cases.

The technique is as follows: The dilator is passed in the lower canaliculus until the bony wall is reached, the anterior rim of the opening of the nasal duct is then made out and the tip of the dilator is placed behind it in the opening of the duct, the handle of the dilator is elevated to an almost perpendicular position and pressed in a downward, outward, and backward direction. A false passage is never made if the above technique is followed out carefully. Should the first dilatation fail to give a result it is done twice more one week apart; if these do not succeed then a leaden style is placed in the lacrymal channel.

A leaden style is about 20 mm. in length, is $1\frac{1}{2}$ mm. in diameter, with an arm bent at right angles that fits in the canaliculus and is 6 mm. in length. To insert it most readily the rapid dilator is first placed in its usual position in the lacrymal channel with its tip in the inferior meatus of the nose. It is then slowly withdrawn and the style is passed down alongside it, replacing the dilator as it is removed. When inserted properly the style is not visible and produces no perceptible irritation. The after-treatment consists in grasping the arm of the style with forceps daily and moving it to prevent the lining of the lacrymal passage from becoming attached to it, and this is followed by flushing the channel with a cleansing solution. After daily treatments for a few weeks no further regular attention will be found necessary. The tendency of the lacrymal channel is to constrict when the style is removed earlier than six months and it is the practice of the writer to allow it to remain even a much longer time.

Seldom is it found necessary to resort to more heoric measures than the placement of a style for the correction of epiphora, but if this does not suffice then the excision of the palebral portion of the lacrymal gland or the extirpation of the lacrymal sac may be done.

When the epiphora is the result of existing inflammations of the lacrymal drainage apparatus one of two diseases is usually present, a chronic catarrhal inflammation of the lacrymal sac (chronic dacryocystitis) with regurgitation of mucoid material into the conjunctival cul de sac, or a phlegmonous dacryocystitis. Should either one of these exist the extirpation of the lacrymal sac becomes imperative and the patient is confronted with the choice of operation.

The extirpation of the lacrymal sac through a facial incision over the sac area (European method) seems to be most in vogue to-day, but in this procedure, if the incision on the face does not heal by first intention a broad scar remains. To obviate the possibility of a facial scar the writer has devised an extirpation operation of the lacrymal sac through the slit canaliculi that has given repeated excellent results. A report of which appeared in the MEDICAL RECORD, August 19, 1916.

In brief the technique is as follows: Ether anesthesia is preferable, but it may be done by injecting a local anesthetic into the skin over the sac. The upper and lower canaliculi are slit and the bridge of tissue that remains between the distal ends of the incisions is severed with a bistoury, the internal canthal ligament is divided at its attachment to the anterior lacrymal crest, then with appropriate curettes the diseased sac and granulation tissue about it are scraped out through the canalicular incisions. A bandage is then applied to keep the walls opposed and prevent swelling. The bandage is renewed for two or three days.

The advantages of this operation are (1) there is no scar remaining on the face; (2) there is less difficulty in obtaining consent to operate when the absence of a facial scar is assured; (3) there is little hemorrhage during the operation; (4) there is no possible return of the condition because the mucous lining is ablated from the punctum to the upper portion of the nasal duct.

Conclusion.—1. Overflowing tears is the result of stenosis of the lacrymal drainage apparatus not attended by inflammation.

(a) A stenosis of the punctum or canaliculus is corrected by a Bowman's slit of the lower canaliculus.

(b) A stenosis of the lacrymal sac or nasal duct is corrected in 25 per cent. of the cases by passing a rapid dilator through the slit canaliculus to the inferior meatus of the nose. Nearly all of the remaining cases are corrected by placing a leaden style in the lacrymal drainage channel and allowing it to remain six months or more. An excision of the palpebral portion of the lacrymal gland or an extirpation of the lacrymal sac is done if the above measures fail to check the overflow of tears.

2. Overflowing tears the result of stenosis of the lacrymal drainage apparatus attended by inflammation.

(a) An extirpation of the lacrymal sac is imperative when the epiphora is the result of a chronic catarrhal or phlegmonous inflammation of the lacrymal sac.

(b) The extirpation operation of preference is the one in which the lacrymal sac is removed through the slit canaliculi.

127 West Fifty-eighth Street.

PYORRHEA ALVEOLARIS.

By M. B. Saunders, M.D.,

Waco, Texas.

This is a very serious and a very common disease, which, according to Barker, Bass, Johns, and others is an amebic infection.

Barker[1] says: "By pyorrhea alaveolaris I mean a disease in which there is inflammation of several structures—the gums, the peridental membrane or ligamentum circulare, and the periosteum, and the alveolar process of the jaw; it is therefore a combined gingivitis, paradentitis, and osteitis; the inflammation may cause destruction as high as the apex of the tooth, and ultimately the tooth falls out. By paradental inflammation is meant an acute inflammation of the periodontium and its neighborhood, not due to extension from the interior of the tooth or the apex of the root-canal, but arising in a gingival pocket. Tartar collects on the teeth at the gum-margin and inflammation of the gum (gingivitis marginalis) develops. As the tartar descends, or ascends, into the alveolar socket, there is gradual atrophy of the gum and alveolus, and later the teeth will become loose and fall out. This process is associated with infection and suppuration. The *Entameba buccalis, spirochetes,* and bacteria can be found in the pus. Inspection and palpation usually settle the diagnosis. The entameba should be sought microscopically. In incipient cases, a skillful dentist may discover "pyorrhea pockets" at a stage when they might be overlooked by the physician. Pyorrhea alveolaris must be differentiated (1) from scorbutic and other forms of "spongy" gums, and (2) from simple atrophia alveolaris praecox (retraction of gums without any signs of inflammation).

"Systemic or toxic sequelæ of this affection are many. I have observed a case in which there was marked enlargement and tenderness of the liver in association with a very severe pyorrhea alveolaris with fever. The liver edge was at the level of the umbilicus. The teeth were loose and bathed in pus. Attempts were made at first to clean up the mouth with antiseptic washes, but they were of no avail, and large quantities of pus were swallowed by the patient. Finally, an anesthetic was given and all the teeth were extracted. In a few days the oral sepsis had been overcome and the temperature fell to normal. The liver, to my surprise, rapidly decreased in size, and a month later the edge was at the costal margin. The general health of the patient rapidly improved."

Chronic arthritis, secondary to pyorrhea, is quite an every-day occurrence with the observing practitioner. Irritable heart, dysentery, and tropical abscess of the liver should not surprise one.
